## 1 Executive Summary

### Stock

This is an update assessment of widow rockfish (*Sebastodes entomelas*) that reside in the waters off California, Oregon, and Washington from the U.S.-Canada border in the north to the U.S.-Mexico border in the south. The most recent benchmark was conducted in 2015 (Hicks and Wetzel 2015) and first updated in 2019 (Adams et al. 2019). This assessment represents the second update assessment of this stock. Widow rockfish inhabit water depths of 25–370 m from northern Baja California, Mexico to Southeastern Alaska. Although catches north of the U.S.-Canada border and south of the U.S.-Mexico border were not included in this assessment, it is not certain if those populations contribute to the biomass of widow rockfish off of the U.S. West Coast, possibly through adult migration and/or larval dispersion. Following the 2015 benchmark assessment (Hicks and Wetzel 2015), this update assessment is based on a single costwide area model.

**Catches**

Historically, fisheries have caught widow rockfish since the turn of the 20th century. Landings in the trawl fishery are estimated to have increased into the 1940s and remained relatively constant and small (below 1,000 mt per year) throughout the 1950s and into the 1960s before the foreign trawl fleet increased catches into the 1970s, with a peak at almost 5,000 mt in 1967. In the late 1970s a midwater trawl fishery developed for widow rockfish and catches increased rapidly with the discovery of large aggregations that form at night.

Total landings of widow rockfish peaked in the early 1980s, increasing from approximately 1,000 metric tons (mt) in 1978 to over 25,000 mt in 1981. The large landings in the early 1980s were curtailed with trip limits beginning in 1982, which resulted in a decline in landings throughout the 1980s and 1990s following sequential reductions in the trip limits. From 2000 to 2003, landings of widow rockfish dropped from over 4,000 mt to about 40 mt and remained low through 2016. Catches increased rapidly following the quota share reallocation in 2017, and have been near or above 10,000 mt in all years between 2018-2024. Midwater trawl gears in groundfish and Pacific Whiting (hake) fisheries account for the majority of the recent catch.

Widow rockfish are a desirable market species and it is believed that discarding was low historically. However, management restrictions (e.g., trip limits) resulted in a substantial amount of discarding beginning in the early 1980s. Trawl rationalization was introduced in 2011. Between 2011 and 2024 very little discarding of widow rockfish is estimated to have occurred. Recent discards in the model informed by data from the West Coast Observer Program (WCGOP), and total catches (discards plus landings) are reported in addition to landings.

Table i: Recent landings for the bottom trawl, midwater trawl, at-sea hake, net, and hook-and-line fisheries and the total landings across fisheries and the total mortality (discards + landings) (mt). 100% mortality is assumed for discards and catch sources are described below.

<b>Year</b>	<b>Bottom Trawl</b>	<b>Midwater Trawl</b>	<b>At-Sea Hake</b>	<b>Net</b>	<b>Hook-and-line</b>	<b>Total Landings</b>	<b>Total Mortality</b>
2016	9.6	588.0	440.8	0.0	0.8	1,039.2	1,039.4
2017	35.9	4,852.1	1,455.2	0.0	2.7	6,345.9	6,361.5
2018	35.9	9,374.3	1,081.3	0.0	1.5	10,493.0	10,522.8
2019	27.9	8,157.9	1,101.6	0.0	2.1	9,289.4	9,315.3
2020	73.6	7,532.2	746.7	0.0	2.7	8,355.2	8,379.6
2021	103.7	10,141.3	617.3	0.0	4.5	10,866.9	10,899.7
2022	126.8	10,839.8	1,119.0	0.1	8.7	12,094.4	12,129.7
2023	82.3	10,228.0	673.2	0.0	7.1	10,990.6	11,023.5
2024	27.6	9,160.8	533.8	0.0	12.9	9,735.1	9,764.1
2025	35.6	9,345.0	1,455.2	0.0	2.7	10,838.5	10,868.1

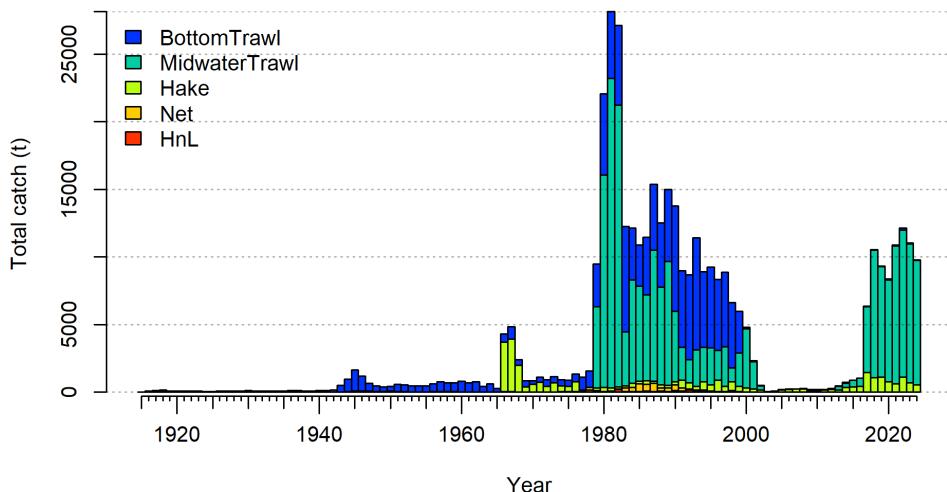

Figure i: Landings of widow rockfish from 1916 to 2024 for bottom trawl, midwater trawl, net, and hook- and-line fisheries, and catches of widow rockfish for the foreign (1966–1976) and Pacific Whiting (hake) fisheries (green).

### Data and Assessment

This assessment uses the length- and age-structured modeling software Stock Synthesis (version 3.30.23.1), while the update assessment in 2019 used 3.30.13. The coastwide population was modeled assuming separate growth and mortality parameters for each sex (a two-sex model) from 1916 to 2024, and forecasted beyond 2024.

Five fishing fleets were specified within the model: 1) a shorebased bottom trawl fleet with coastwide catches from 1916–2024, 2) a shorebased midwater trawl fleet with coastwide catches from 1979–2024, 3) a mostly midwater trawl fleet that targets Pacific Hake/Whiting (*Merluccius productus*) and includes a foreign and at-sea fleet with catches from 1975–2024, a domestic shorebased fleet that targeted Pacific Hake with catches from 1991–2024, and foreign vessels that targeted Pacific Hake and rockfish between 1966–1976, 4) a net fishery consisting of catches mostly from California from 1981–2024, and 5) a hook-and-line fishery (predominantly longline) with coastwide catches from 1916–2024. Landings are summarized in Figure i.

Data from three fishery-independent surveys were also included in the model: 1) the National Marine Fisheries Service (NMFS) Southwest Fisheries Science Center (SWFSC) and Northwest Fisheries Science Center (NWFSC)/Pacific Whiting Conservation Cooperative (PWCC) Midwater Trawl Survey that provides pre-recruit indices of abundance from 2004–2024, 2) the NMFS Triennial Shelf Survey which was conducted from 1977–2004

in depths less than 500 meters, and 3) the NWFSC West Coast Groundfish Bottom Trawl Survey (WCGBTS) which has been surveying the entire U.S. West Coast in depths between 55 and 1,280 meters since 2003. Three historical fishery-dependent CPUE indices were included as in the 2015 and 2019 assessments, derived from 1) Oregon bottom trawl (1984-1999), 2) Pacific Whiting at-sea foreign (1977-1988), and 3) Pacific whiting at-sea domestic fleets (1983-1998).

The data used in the assessment model consisted of survey abundance indices, length compositions, discard data, and age compositions. Model-based biomass indices and length compositions were determined for the NMFS Triennial Shelf and NWFSC West Coast Groundfish Bottom Trawl Surveys. Length and age compositions were also available from the five fisheries. Age data for all years of the WCGBTS were input as age-at-length compositions. Discard data for the bottom trawl, midwater trawl, and hook-and-line fisheries were available in various years in the form of discarded biomass and length compositions.

The base model estimated parameters for length-based selectivity for all fleets and surveys, retention curves based on length for the bottom trawl and midwater trawl fleets, a length-at-age relationship, natural mortality for males and females assuming lognormal priors, and recruitment deviations starting in 1900. A Beverton-Holt stock-recruitment function was used to model productivity and the steepness parameter was fixed at 0.72 based on a steepness meta-analysis for west coast rockfishes.

Estimation uncertainty in the base model was determined using approximate asymptotic 95% confidence intervals based on maximum likelihood theory. Natural mortality and steepness are major sources of uncertainty. We used high and low combinations of these parameters to define a range of states of nature, with results presented in a decision table.

### **Stock biomass and dynamics**

The predicted spawning biomass from the base model generally showed a slight decline over the time series until 1966 when the foreign fleet began. A short, but sharp decline occurred, followed by a steep increase (peaking in 1979) due to strong recruitment. The spawning biomass declined rapidly with the developing domestic midwater fishery in the late 1970s and early 1980s. The stock continued to decline until 2000. A combination of strong recruitment and low catches resulted in a steady increase in spawning biomass through 2016. A target fishery for widow rockfish was reestablished in 2017. The stock exhibits a decline in most recent years with the increased catches since 2017, and lack of evidence for recent large recruitment events.

The 2024 spawning stock biomass (SSB) relative to unfished equilibrium spawning biomass is at 55, above the target of 40%.

Approximate confidence intervals based on the asymptotic variance estimates show that the uncertainty in the estimated spawning biomass is high, especially in the early years. Spawning biomass is estimated to be at 45,046 mt in 2024, with an asymptotic 95% confidence interval of 45,046 - 45,046. The corresponding confidence interval for the relative SSB is 55.3% - 55.3%, for which the lower bound is below the management target of 40%.

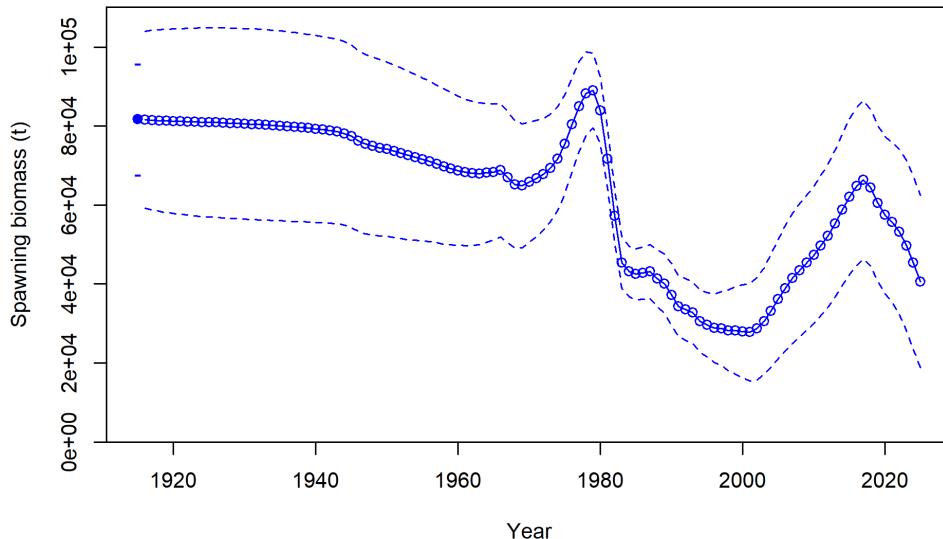

Figure ii: Estimated female spawning biomass time-series from the base model (solid line) with an approximate asymptotic 95% confidence interval (dashed lines).

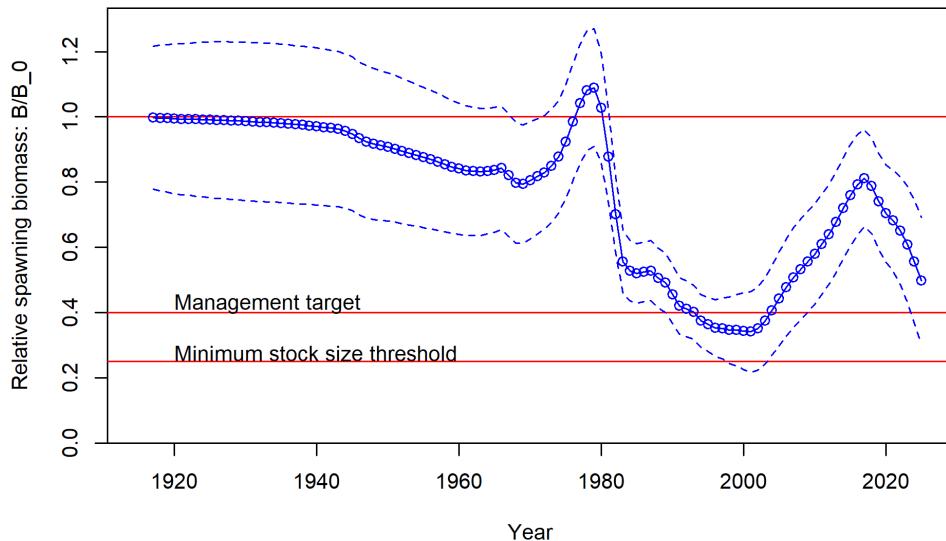

Figure iii: Estimated relative spawning biomass (depletion) with approximate 95% asymptotic confidence intervals (dashed lines) for the base case assessment model.

Table ii: Recent trend in estimated female spawning biomass (mt) and relative spawning biomass (depletion).

<b>Year</b>	<b>Spawning Biomass</b>	<b>95% Confidence Interval</b>	<b>Estimated Depletion (%)</b>	<b>95% Confidence Interval</b>
2016	64,261	64,261 - 64,261	0.788677	0.789 - 0.789
2017	65,863	65,863 - 65,863	0.808343	0.808 - 0.808
2018	63,934	63,934 - 63,934	0.784662	0.785 - 0.785
2019	60,055	60,055 - 60,055	0.737058	0.737 - 0.737
2020	57,126	57,126 - 57,126	0.701113	0.701 - 0.701
2021	55,346	55,346 - 55,346	0.679266	0.679 - 0.679
2022	52,884	52,884 - 52,884	0.649048	0.649 - 0.649
2023	49,359	49,359 - 49,359	0.605791	0.606 - 0.606
2024	45,046	45,046 - 45,046	0.552851	0.553 - 0.553
2025	40,184	40,184 - 40,184	0.493175	0.493 - 0.493
2026	34,268	34,268 - 34,268	0.420573	0.421 - 0.421

## Recruitment

Recruitment deviations were estimated for the entire time series modeled. There is little information regarding recruitment prior to 1965, and the uncertainty in these estimates is expressed in the model.

There are several very large, but uncertain, estimates of recruitment (in descending order of magnitude) in 1970, 2008, 2016, and 1971. Other large recruitment events (in descending order of magnitude) occurred in 1978, 1981, 2010, and 1991.

The five lowest recruitments (in ascending order) occurred in 2012, 2019, 2020, 2011, and 1976. Estimates of recruitment appear to be episodic and characterized by periods of low recruitment.

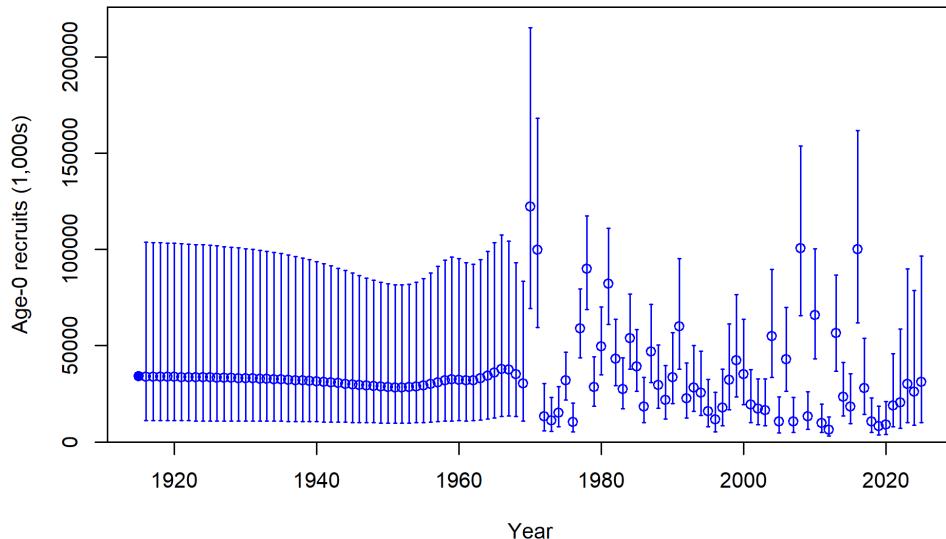

Figure iv: Time-series of estimated recruitments (medians as open circles) for the base case model with approximate asymptotic 95% confidence interval (vertical bars). Estimated mean unfished equilibrium recruitment ( $R_0$ ) is shown as the closed circle with a 95% confidence interval at the beginning of the time series.

Table iii: Recent estimated trend in widow rockfish recruitment with approximate 95% confidence intervals determined from the base model.

<b>Year</b>	<b>Estimated recruitment (number in thousands)</b>	<b>95% Confidence Interval</b>	<b>Recruitment Deviations</b>	<b>95% Confidence Interval</b>
2016	98,971	98,971 - 98,971	1.249	1.249, 1.249
2017	27,557	27,557 - 27,557	-0.033	-0.033, -0.033
2018	10,482	10,482 - 10,482	-1.014	-1.014, -1.014
2019	8,202	8,202 - 8,202	-1.273	-1.273, -1.273
2020	8,835	8,835 - 8,835	-1.214	-1.214, -1.214
2021	18,753	18,753 - 18,753	-0.478	-0.478, -0.478
2022	20,353	20,353 - 20,353	-0.412	-0.412, -0.412
2023	29,951	29,951 - 29,951	-0.037	-0.037, -0.037
2024	25,888	25,888 - 25,888	-0.189	-0.189, -0.189
2025	30,867	30,867 - 30,867	0.000	0, 0
2026	29,941	29,941 - 29,941	0.000	0, 0

### Exploitation status

The spawning biomass of widow rockfish reached a low in 2001 before increasing due to low catch levels.

The lower bound of the 95% confidence interval of the estimated depletion dipped below the overfished threshold (25% minimum stock size threshold) in the very late 1990s and early 2000s. After recovering after 2016, the lower bound of the 95% confidence interval dipped below the 40% management target in 2024 but remains above the overfished threshold. The current depletion point estimate is greater than the spawning biomass target.

Table iv: Recent trend in spawning potential ratio and summary exploitation rate. Harvest rate is defined as catch divided by age 4+ biomass.

Year	Estimated (1-SPR)/(1- SPR50%)	~95% Confidence Interval	Harvest rate (proportion)	~95% Confidence Interval
2016	0.163	0.163 - 0.163	0.008	0.008, 0.008
2017	0.742	0.742 - 0.742	0.050	0.05, 0.05
2018	1.078	1.078 - 1.078	0.086	0.086, 0.086
2019	1.060	1.06 - 1.06	0.083	0.083, 0.083
2020	1.046	1.046 - 1.046	0.073	0.073, 0.073
2021	1.214	1.214 - 1.214	0.097	0.097, 0.097
2022	1.275	1.275 - 1.275	0.117	0.117, 0.117
2023	1.256	1.256 - 1.256	0.120	0.12, 0.12
2024	1.267	1.267 - 1.267	0.122	0.122, 0.122
2025	1.438	1.438 - 1.438	0.154	0.154, 0.154

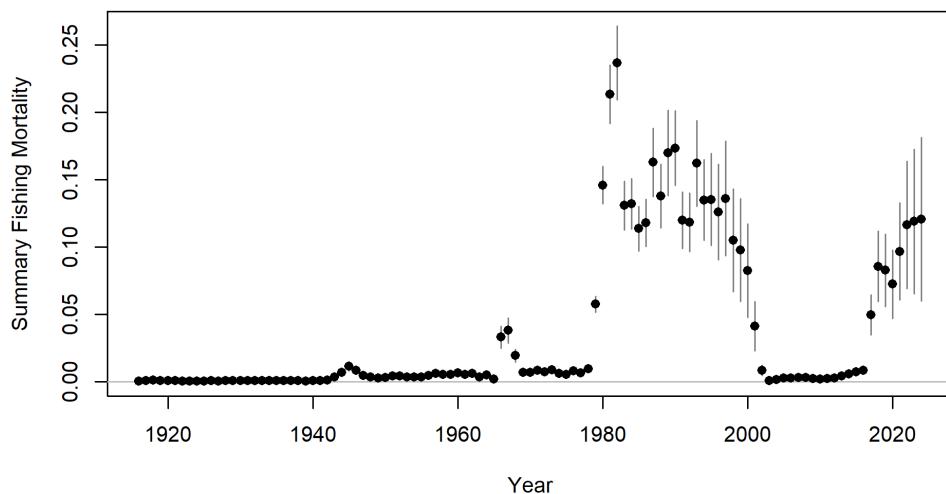

Figure v: Time-series of estimated summary harvest rate (catch divided by age 4+ biomass) for the base case model (round points) with approximate 95% asymptotic confidence intervals (gray lines).

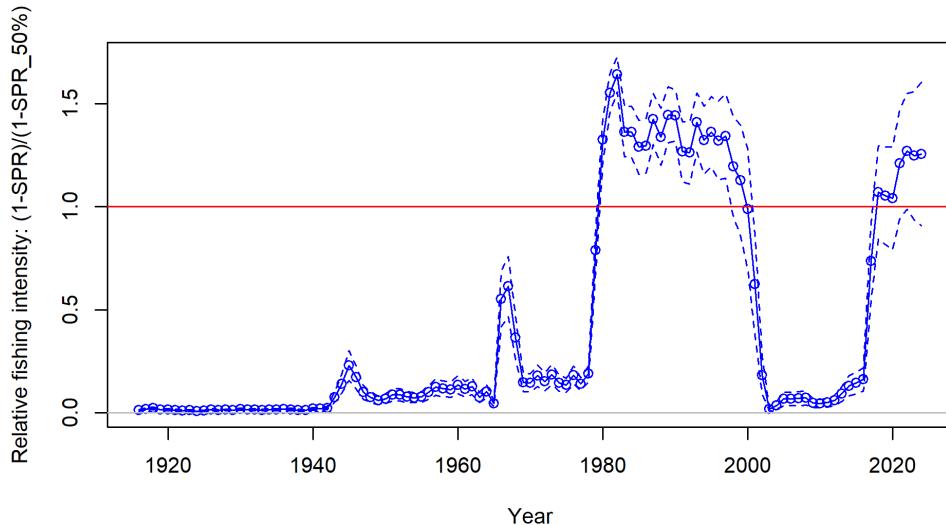

Figure vi: Trend in estimated fishing intensity (relative to the SPR management target) through 2024 with 95% asymptotic confidence intervals. One minus SPR is used so that higher exploitation rates occur on the upper portion of the y-axis. The relative management target is plotted as a horizontal line and values above this reflect harvests in excess of the overfishing proxy based on SPR50%.

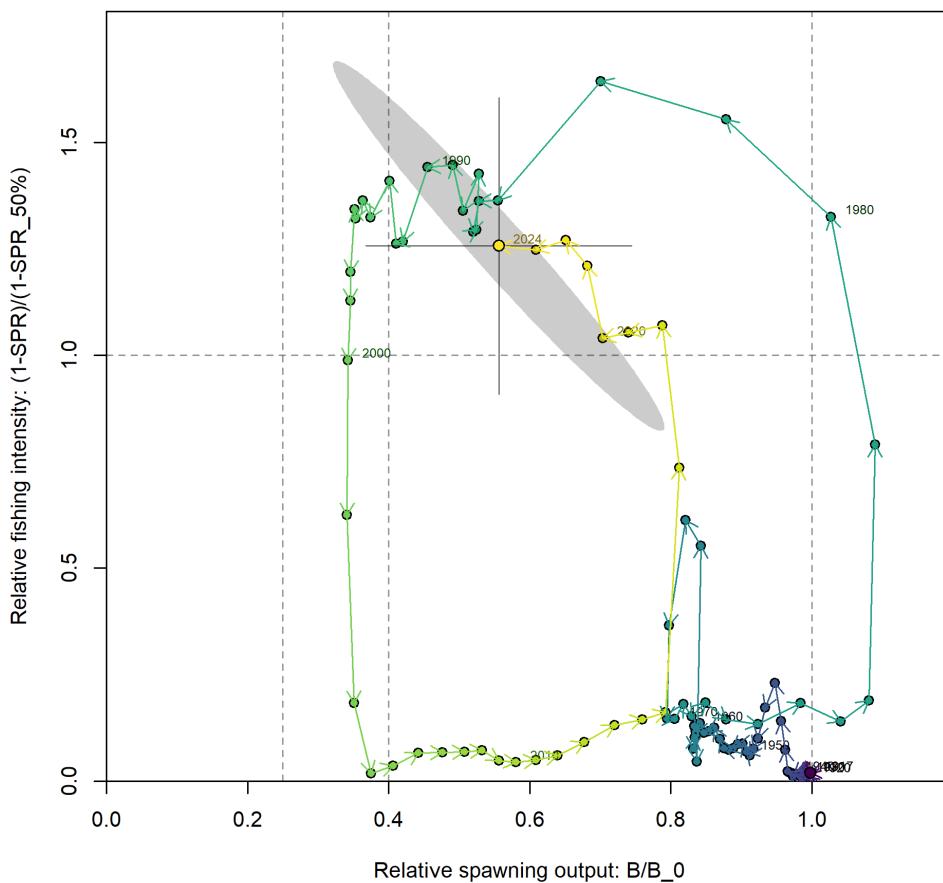

Figure vii: Phase plot of estimated relative fishing intensity relative biomass for the base case model. The relative (1- SPR) is  $(1-SPR)$  divided by 0.5 (one minus the SPR target). Lines through the final point (2024) show 95% intervals based on the asymptotic uncertainty for each dimension. The shaded ellipse is a 95% region which accounts for the estimated correlation between the two quantities.

### Ecosystem considerations

Rockfish (*Sebastodes* spp.) are an important component of the California Current ecosystem along the U.S. West Coast, comprising more than sixty-five species filling various niches in both soft and hard bottom habitats from the nearshore to the continental slope, as well as near bottom and pelagic zones. Widow rockfish frequently aggregate in the pelagic zone.

Recruitment is one mechanism by which the ecosystem may directly impact the population dynamics of widow rockfish. The specific pathways through which environmental conditions exert influence on widow rockfish dynamics are unclear; however, changes in water temperature and currents, distribution of prey and predators, and the amount and timing of upwelling are all possible linkages. Changes in the environment may also result in changes in age-at-maturity, fecundity, growth, and survival which can affect how the status of the stock and its susceptibility to fishing are determined. Unfortunately, there are few data available for widow rockfish that provide insights into these effects.

Fishing has effects on both the age structure of a population as well as the target species habitat. Fishing often targets larger, older fish, and years of fishing mortality results in a truncated age-structure when compared to unfished conditions. Rockfish are often associated with habitats containing living structures such as sponges and corals, and fishing may alter that habitat to a less desirable state. This assessment provides insight on the effects of fishing on age structure, and recent studies on essential fish habitat are beginning to characterize important locations for rockfish throughout their life history; however there is little current information available to evaluate the specific effects of fishing on the ecosystem issues specific to widow rockfish.

### **Reference points**

Reference points were calculated using the estimated selectivities and average catch distribution among fleets in the most recent five years of the model (2019-2024). Total yields (landings plus discards) were 5,594 mt when using an SPR50% reference harvest rate and with a 95% confidence interval of 5,594 to 5,594 mt. The spawning biomass equivalent to 40% of the unfished spawning output (SB40%) was 32,592 mt. Catches between the late 1990's and 2016 were well below the point estimate of potential long-term yields calculated using an SPR50% reference point, and the population is estimated to have increased continuously throughout that time period. However, catches from 2017 through 2024 were above the point estimate of potential long-term yields using an SPR50% reference point, exceeding the upper bound of the confidence interval in all years since 2018, and exceeding the point estimate by on average NaN%.

The predicted spawning biomass from the base model generally showed a slight decline until the late 1970s, followed by steep increase above unfished equilibrium biomass and reaching a peak in 1979. This was followed by a steep decrease up to the mid-1980s, and then a more gradual decease through 2000 (Figure [iii](#)). Between 2001 and 2016, the spawning biomass increased continuously due to small catches, and several years of high recruitment (though with lower than average recruitment in other recent years). The spawning biomass relative to unfished equilibrium spawning biomass climbed above the target of 40% of unfished spawning biomass in the early 2000's. It is estimated to still be above the target, though the lower bound of the 95% confidence interval lies between the target and minimum stock size threshold (Figure [iii](#)). The fishing intensity (relative 1-SPR) exceeded the current estimates of the harvest rate limit (SPR50%) throughout

the 1980s and early 1990s, and has again since 2018 (Figure v). Exploitation rates on widow rockfish between 2001 and 2016 were predicted to be far below target levels. In recent years, the stock has experienced exploitation rates that have been above the target level while the biomass level has remained above the target level (Figure vii).

The equilibrium yield plot is shown in Figure viii, based on a steepness value fixed at 0.72. The predicted maximum sustainable yield under the assumptions of this assessment occurs near 25% of equilibrium unfished spawning biomass.

Table v: Summary of reference points and management quantities for the base case model.

Reference Point	Estimate	Lower Interval	Upper Interval
Unfished Spawning Biomass (mt)	81,479.20	81,479.20	81,479.20
Unfished Age 4+ Biomass (mt)	151,093.00	151,093.00	151,093.00

MSY (mt)	6,270.27	6,270.27	6,270.27

### **Management performance**

Exploitation rates on widow rockfish exceeded MSY proxy target harvest rates during the 1980s and 1990s and spawning biomass is predicted to have fallen below the proxy management target of 40%. Exploitation rates decreased in the late 1990s due to management restrictions, and have increased in recent years. Predicted catches in the last decade have not exceeded the annual catch limit (ACL) set by management.

Table vi: Recent trend in total catch and commercial landings (mt) relative to the management guidelines. Estimated total catch reflects the commercial landings plus the model estimated dead discarded biomass.

<b>Year</b>	<b>OFL (mt)</b>	<b>ABC (mt)</b>	<b>ACL (mt)</b>	<b>Landings (mt)</b>	<b>Total Mortality (mt)</b>
2016	3,990	3,790.00	2,000	1,039.24	1,039.41
2017	14,130	13,508.28	13,508	6,345.89	6,361.45
2018	13,237	12,654.57	12,655	10,493.03	10,522.76
2019	12,375	11,830.50	11,831	9,289.43	9,315.27
2020	11,714	11,198.58	11,199	8,355.24	8,379.58
2021	15,749	14,725.32	14,725	10,866.89	10,899.73

2025	12,254	11,236.92	11,237	10,838.45	10,868.09

### **Harvest projections and decision table**

Two categories of parameters that greatly contributed to uncertainty in the results were natural mortality (an important estimated parameter) and steepness (not estimated in the model). A combination of these two factors was used as the axis of uncertainty to define low and high states of nature. This differed from the 2019 assessment which included a third factor, 2013 recruitment strength. The 12.5% and 87.5% quantiles for female and male natural mortality (independently) were chosen as low and high values ( $0.115 \text{ yr}^{-1}$  and  $0.134 \text{ yr}^{-1}$  for females;  $0.127 \text{ yr}^{-1}$  and  $0.146 \text{ yr}^{-1}$  for males). Steepness is probably the most important factor since it was fixed in the base model and is not incorporated in the estimation uncertainty. The 12.5% and 87.5% quantiles from the steepness prior (without widow rockfish data) were used to define the low and high values

of steepness (0.536 and 0.904). The low combination of these two factors defined the low state of nature and the high combination of these two factors defined the high state of nature. The predictions of spawning biomass in 2025 from the low and high states of nature are close to the 12.5% and 87.5% lognormal quantiles from the base model.

This assessment synthesizes many sources of data and estimates recruitment variability, thus it is classified as a Category 1 stock assessment. Therefore, the sigma to determine the catch reduction to account for scientific uncertainty is 0.50.

A twelve year projection of the base model with two catch streams based on ACL adjustments of 0.45 P\* and 0.25 P\* were conducted (Table [viii](#)).

Projections with catches based on the predicted annual catch limit (ACL) using the SPR rate of 50%, the 40:10 control rule, and a 0.45 P\* adjustment using a sigma of 0.50 from 2027 onward suggest that the spawning biomass will decrease over the projection period for all states of nature (Table [viii](#)). Predicted ACL catches range from 3,231 mt in 2027 to 4,392 mt in 2036.

Projections with catches based on the predicted annual catch limit (ACL) using the SPR rate of 50%, the 40:10 control rule, and a 0.25 P\* adjustment using a sigma of 0.50 from 2027 onward suggest that the spawning biomass will decrease over the projection period for all states of nature. Predicted ACL catches range from 1,790 mt in 2027 to 1,886 mt in 2036.

Table vii: Projection of potential OFL, landings, and catch, summary biomass (age-4 and older), spawning biomass, and depletion for the base case model projected with total catch equal to the predicted ABC. The predicted OFL is the calculated total catch determined by FSPR=50%.

Year	Adopted OFL (mt)	Adopted ACL (mt)	Assumed Catch (mt)	OFL (mt)	Buffer	ABC (mt)	ACL (mt)	Spawning Biomass (mt)	Fraction Unfished

**Scientific uncertainty**

Spawning biomass is estimated to be at 40,184 mt in 2025, with a sigma of 0.2769. OFL is estimated to be 5,565 mt in 2019 with a coefficient of variation of 0.3126

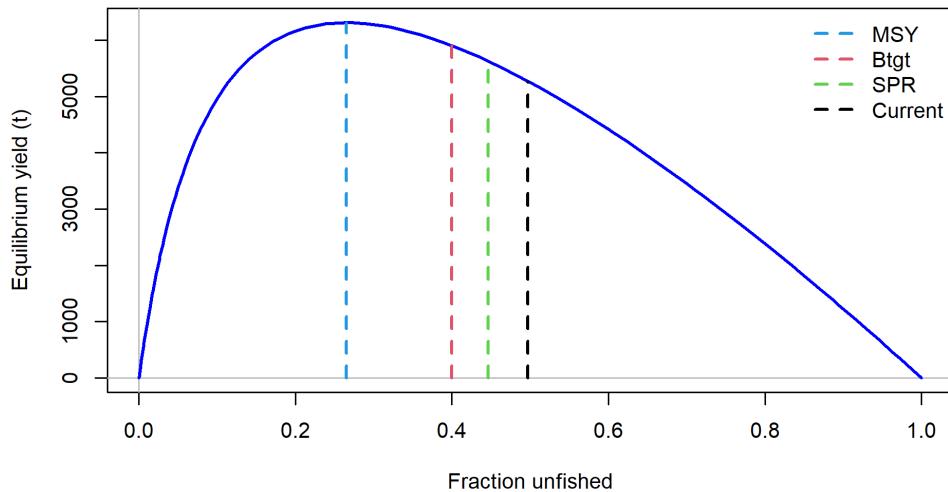

Figure viii: Equilibrium yield curve for the base case model and associated target and limit reference points. Values are based on most recent fishery selectivity and distribution with steepness fixed at 0.720. The fraction unfished is relative to unfished spawning biomass.

## 1 Introduction

This is an assessment of widow rockfish that inhabit the waters off California, Oregon, and Washington from the U.S.-Canadian border in the north to the U.S.-Mexico border in the south, and does not include Puget Sound.

*Sebastodes entomelas* (widow rockfish) is named after its black-lined gut cavity (*ento* meaning within and *melas* meaning black). It has been referred to as buda, beccafico (Italian bird), and viuva (widow) prior to the 1930s. More recently, the widow rockfish is also called brownie, belinda bass, brown bomber, and soft brown.

### 1.1 Distribution and Stock Structure

Widow rockfish inhabit water depths of 25–370 m from northern Baja California, Mexico to Southeastern Alaska, and are most abundant from British Columbia to Northern California. Although catches north of the U.S.-Canada border or south of the U.S.-Mexico border were not included in this assessment, it is possible that these populations contribute to the biomass of widow rockfish off of the U.S. West Coast through adult migration and/or larval dispersion.

This assessment is based on a single coastwide area model. There is little evidence of genetically separate stocks along the U.S. coast and past assessments have used a single area versus a two-area assessment model and results were found to be similar (He et al. 2011). There is some evidence of biological differences between areas. For example, widow rockfish collected off California tend to mature at a smaller length than widow rockfish collected off of Oregon (Barss and Echeverria 1987). This may be due to environmental or anthropogenic effects rather than genetic differences.

### 1.2 Life History

This section is not required for an update assessment; please refer to the most recent full assessment (Hicks and Wetzel 2015) for additional information.

### 1.3 Ecosystem Considerations

This section is not required for an update assessment; please refer to the most recent full assessment (Hicks and Wetzel 2015) for additional information.

#### **1.4 Fishery description**

This section is not required for an update assessment; please refer to the most recent full assessment (Hicks and Wetzel 2015) for additional information.

#### **1.5 Management History**

This section is not required for an update assessment; please refer to the most recent full assessment (Hicks and Wetzel 2015) for additional information.

#### **1.6 Management performance**

Total mortality estimates from the WCGOP and from the stock assessment may differ due to the use of different methods. Investigation into how these methods differ is beyond the scope of a benchmark assessment. Table 3 shows that recent landings have been below recommended catch levels. Landings are a considerable amount below the ACL, and it is unlikely that total mortality has exceeded the ACL in the last 10 years.

#### **1.7 Fisheries off Canada and Alaska**

This section is not required for an update assessment; please refer to the most recent full assessment (Hicks and Wetzel 2015) for additional information.

## 2 Data

Many sources of data were available for this assessment (Figure 23), including indices of abundance, landings, discards, and length and age observations from fishery-dependent and fishery-independent sources. Data used in this assessment are described below. No new data sources were considered in this update assessment.

### 2.1 Fishery-independent data

Data from three fishery-independent surveys were used in this assessment: 1) the SWFSC and NWFSC/PWCC Midwater Trawl Survey (hereafter, “juvenile survey”); 2) the Alaska Fisheries Science Center (AFSC)/NWFSC Triennial Shelf Trawl Survey (hereafter, “triennial survey”); and 3) the NWFSC West Coast Groundfish Bottom Trawl Survey (hereafter, “WCGBTS”). Depth and latitude strata used to analyze the catch-rates, length compositions, and age compositions are the same as in the 2019 assessment (Adams et al. (2019), Table 10).

#### 2.1.1 Alaska Fisheries Science Center/Northwest Fisheries Science Center West Coast Triennial Shelf Survey

The Alaska Fisheries Science Center/Northwest Fisheries Science Center West Coast Triennial Shelf Survey (Triennial Survey) was first conducted by the Alaska Fisheries Science Center (AFSC) in 1977 and was conducted every three years, ending 2004. The survey’s design and sampling methods are most recently described in (Weinberg et al. 2002).

The time series suggests a possible slightly increasing trend in biomass from 1980–1983, although is relatively flat until the end of the period in 2001 and 2004 when the index declines significantly. The index and length compositions for this historical Triennial survey were unchanged from the previous assessment. Please refer to to Hicks and Wetzel (2015) for details on those data inputs.

#### 2.1.2 Northwest Fisheries Science Center West Coast Groundfish Bottom Trawl Survey

The Northwest Fisheries Science Center West Coast Groundfish Bottom Trawl Survey (Northwest Fisheries Science Center West Coast Groundfish Bottom Trawl Survey (WCG-BTS)) has been conducted annually, since 2003. It is based on a random-grid design; covering the coastal waters between depths of 55–1,280 m (Bradburn et al. 2011). No survey occurred in 2020 due to Coronavirus disease (COVID-19). Widow rockfish are

not commonly caught in the WCGBTS. Higher catch rates occur north of 40° N latitude and catches are rare south of 36° N latitude. Few large fish are found shallower than 100 m and few small fish are found in the deeper water of the slope. There is no clear trend in length with latitude other than smaller fish tend to occur south of approximately 36° N latitude, and there appears to be some very small fish found near 39° N latitude.

For this assessment, geostatistical models of biomass density were fit to survey data using the R package [Species Distribution Models with Template Model Builder \(sdmTMB\)](#) (Anderson et al. 2022). This is an updated approach compared to the 2015 assessment (non-spatial delta-GLMM) and the 2019 update assessment (VAST delta-lognormal model). The sdmTMB model used a 200 knot mesh of the survey area (Thorson et al. 2015). The prediction grid was truncated to only include available survey locations in depths between 55–500 m to limit extrapolating beyond the data and edge effects. Tweedie, delta-binomial, delta-gamma, and mixture distributions, which allow for extreme catch events, were investigated. The positive catch weight model includes survey pass ('first' for early season or 'second' for late season) and year. Vessel-year effects, which have traditionally been included in index standardization for this survey, were not included as the estimated variance for the random effect was close to zero. Vessel-year effects were more prominent when models did not include spatial effects and were included for each unique combination of vessel and year in the data to account for the random selection of commercial vessels used during sampling (Helser et al. 2004; Thorson and Ward 2014).

Results are only shown for the delta-gamma and delta-lognormal distributions, which reported the best diagnostics among the explored models (Figure 2). Both models converged (positive definite Hessian matrix) but predicted data from both models showed slightly right-heavy tails compared to null expectations, with the gamma model having stronger divergence. Spatiotemporal estimates of positive catch for the delta-lognormal distribution were then converted into annual indices using `sdmtmb::get_index()` function informed by the spatial bounds of the survey (Anderson et al. 2022).

Overall, the delta-lognormal index estimates is more comparable to the 2019 spatiotemporal VAST-based index than the delta-gamma index, and less influenced by extreme catch events, particularly in 2013 and 2016; for these reasons, in addition to better model performance observed above, the delta-lognormal sdmTMB-based index was used for the base model in this assessment. The delta-lognormal mean value (2262.824) was slightly lower than the means of the index values used in the 2015 assessment (2701.12) and the 2019 update assessment (3301.765). Comparisons of the different error structures, design-based estimate and the VAST index used in 2019 are in Figure 3.

Length, age, and conditional age-at-length compositions were processed using the `nwfscSurvey` package in R publicly available on GitHub (Wetzel et al. 2025). Length compositions were created by expanding to the tow and summing to give a strata specific composition (Table 7). Strata definition was retained from the benchmark assessment. The strata compositions were combined to a coastwide composition using a design-based

index of abundance from each strata. The design based index is constructed by taking the average catch per unit effort (CPUE) defined as catch per area swept across tows in each stratum and year. The sum of strata specific composition data was then calculated, weighting by the average CPUE per stratum multiplied by the area of each stratum. Age distributions were included in the model as conditional-age-at-length (CAAL) observations. The marginal age-compositions were also included, but only for easier viewing of strong cohorts. The CAAL data were not expanded and were binned according to length, age, sex, and year.

The input sample sizes for length and marginal age-composition data were calculated based on (Stewart and Hamel 2014). The input sample size of CAAL data was set at the number of fish at each length by sex and by year. Expanded length frequencies from this survey show intermittent years of small fish; the 2018–2024 period generally suggests most fish are around 40–45cm in length (Figure 4). Strong cohorts are not immediately apparent and it seems that ageing error may result in some variability between years. Conditional age-at-length proportions (Figure 6) show relatively consistent length-at-age with few outliers.

### 2.1.3 SWFSC and NWFSC/PWCC Midwater Trawl Survey

An updated coastwide pre-recruit index of abundance for 2001–2024 for widow rockfish was created using data from three midwater trawl surveys targeting young-of-the-year (YOY) rockfish (SWFSC and NWFSC/PWCC Midwater Trawl Survey (Juvenile Survey)), provided by Tanya Rogers (SWFSC, pers. comm.). All surveys used identical gear, enabling the construction of a consistent coastwide index spanning from 36°N to the U.S./Canada border since 2004. Sampling in 2020 was limited due to the COVID-19 pandemic and excluded from all models. In 2010 and 2012, coverage was incomplete, so these years excluded from the final model to align with the 2019 assessment. Following the 2015 and 2019 assessments, data from 2001–2003 were also excluded due to limited spatial coverage (36°30' to 38°20' N latitude).

The index was built using a spatial GLM with the sdmTMB package (Anderson et al. 2022), modeling 100-day standardized catch-per-tow as a function of year (fixed effect), Julian date (GAM smoother,  $k = 4$ ), spatial random field, and spatiotemporal random effects. Models with Tweedie, delta-lognormal, and delta-gamma error structures were compared; DHARMA residuals and simulation-based diagnostics indicated the Tweedie model performed best. The index shows a strong increasing trend in juvenile abundance from 2017 to 2023, with a slight decline in 2024. Recent values remain high relative to the previous decade, and uncertainty estimates support the robustness of this trend.

## 2.2 Fishery-dependent data

### 2.2.1 Landings

Widow rockfish is primarily caught by bottom trawl and midwater trawl gears (Table 1). This species also commonly bycaught by fishery targeting Pacific hake. Minimal amounts are also taken by non-trawl gears such as hook-and-line and net (Table 9).

The definitions of fishing fleets have not been changed from those in the 2015 and 2019 assessments. Five fishing fleets were specified within the model: 1) a shorebased bottom trawl fleet with coastwide catches from 1916–2024, 2) a shorebased midwater trawl fleet with coastwide catches from 1979–2024, 3) a mostly midwater trawl fleet that targets Pacific Hake/Whiting (*Merluccius productus*) and includes a foreign and at-sea fleet with catches from 1975–2024, a domestic shorebased fleet that targeted Pacific Hake with catches from 1991–2024, and foreign vessels that targeted Pacific Hake and rockfish between 1966–1976, 4) a net fishery consisting of catches mostly from California from 1981–2024, and 5) a hook-and-line fishery (predominantly longline) with coastwide catches from 1916–2024. As in previous assessments, catches from Puget Sound and those from commercial shrimp trawls, commercial pots, and recreational fisheries were excluded (as these are generally minimal).

Landings from the 1916-2018 period were carried forward into this assessment with slight modifications to the midwater and bottom trawl catches from California. Because PacFIN appear to underestimate midwater trawl catches in California in 1979-1980 when midwater trawl fishery for widow rockfish developed (Edward Dick, Pers. Comms.) we adjusted midwater and bottom trawl catches from California in these years to reflect the ratio of California midwater to bottom trawl catches in 1981-1982.

Recent catches (2019-onward) were extracted from PacFIN for commercial shorebased data and NORPAC for at-sea hake fishery bycatch, and were otherwise appended onto the 1916-2018 landings and apportioned among fleets using the same criteria as those documented in the 2015 assessment Hicks and Wetzel (2015).

### 2.2.2 Fishery catch-per-unit-effort

Three fishery-dependent CPUE indices were included as in the last assessment (Adams et al. 2019). Indices were derived from 1) Oregon bottom trawl (1984-1999), 2) Pacific Whiting at-sea foreign (1977-1988), and 3) Pacific whiting at-sea domestic fleets (1983-1998). These were not updated; see Adams et al. (2019) for details.

### 2.2.3 Fishery length and age data

Biological data from commercial fisheries that caught widow rockfish were extracted from PacFIN on March 25, 2025 and from the NORPAC database. Lengths and age samples taken during port sampling in California, Oregon, and Washington were used to generate length and age compositions. The data were classified into bottom trawl, midwater trawl, hake trawl, net, and hook-and-line fleets using pacfintools package in R. For each fleet, the raw observations were expanded to the trip level, to account for differences in samples sizes relative catch weights among trips (first stage expansion). The expanded length observations were then further expanded to state level, to account for differences in sampling intensity of widow rockfish landings among states combined into a single fleet (second stage expansion).

Table 4 shows the number of trips sampled and Table 5 shows the number of lengths taken for each year, gear, and fleet from the three states. Table 6 shows these numbers for the at-sea fleet. Expanded length compositions for bottom trawl, midwater trawl, hake fisheries, net, and hook-and-line are shown in Figure 7 to Figure 11. Age compositions for the five fleets are shown in Figure 12 and Figure 16. Occasional cohorts appear to move through the population, indicating that widow rockfish population dynamics may be characterized by episodic recruitment events.

### 2.2.4 Discards

Data on discards on widow rockfish are available from three different sources. Historical sources included (Pikitch et al. 1988) and Enhanced Data Collected Project (EDCP, Sampson 2002). These historical sources were not reanalyzed for this update assessment, and discard amounts were not changed from the last assessment. Sex-specific length frequencies were also available from (Pikitch et al. 1988). Discard estimates are shown in Table 9 and range from 463 to 1,847 mt. Length compositions for discards show a wide range of sizes being discarded, with a peak around 40 cm (Figure 17).

The West Coast Groundfish Observer Program (WCGOP) provided information on recent discard of widow rockfish between 2002–2023. Since 2011, under trawl rationalization, 100% observer coverage is required for the limited entry trawl sectors, which resulted in a large increase in data and ability to determine discard behavior.

Discard length data for 2004–2023 was provided by WCGOP. In 2015 and 2019 assessments, these data were used to estimate retention curves for bottom trawl and hook-and-like fleets. WCGOP discard lengths from 2004–2017 are unchanged for the bottom trawl fleet, and new data are added for all consecutive years through 2023.

Major changes occurred only in the treatment of the hook-and-line discard data; discards from the hook-and-line fleet were combined with landings into the removals for this fleet. Discard lengths for the hook & line fleet provided by WCGOP this year were corrected to omit nearshore fixed gear fleets, which were included with the hook-and-line fleet in the previous benchmark and update assessments erroneously. This change resulted in changes to the discard length distribution and years for which data was available (Figure 19). The hook-and-line removals comprised only approximately 0.2% of the total removals over the last twenty years (Table 1), with discard being a small fraction of that. The biological samples of the discard amount are also scarce, with input sample sizes not exceeding 6 and averaging around 3 per year. With this limited data, the model was unable to reliably estimate retention parameters and exhibited substantial sensitivity to even slight changes in discard amounts within the hook-and-line fleet. Therefore, in this assessment, we added the hook-and-line discard to hook-and-line landings.

Discard length composition data became available this year for the midwater trawl fleet, but was not available for previous assessments. These newly available data for midwater fleets (hake, rockfish) beginning in 2016, were not included in this updated assessment as this would require major changes to the model structure which are beyond the scope of this update assessment but will need to be considered in the next full assessment.

Figure 17 shows discard sources and totals in metric tons for each year. Coefficients of variation (CV) are set to 5% for years/fleets with 100% observer coverage. Length compositions of the discards for the bottom trawl fleet can be seen in Figure 18.

## 2.2.5 Biological data

The approach to the estimation of all biological parameters was the same as in Adams et al. (2019).

### 2.2.5.1 Weight-length relationship

Weight-at-length data were updated for this assessment. Following the approach used in the 2015 benchmark, data used to estimate the length-weight relationship for widow rockfish were gathered from commercial catch sampling schemes (PACFIN, ASHOP) and fishery-independent surveys (Triennial and WCGBT Survey).

The following relationships between weight and length for females and males were used in the current assessment:

$$\text{Females: } \text{weight} = 1.7355 \times 10^{-5} \cdot \text{Length}^{2.9617}$$

$$\text{Males: } \textit{weight} = 1.4824 \times 10^{-5} \cdot \textit{Length}^{3.0047}$$

where weight is measured in kilograms and length in cm. These parameters were used in the assessment as fixed.

#### **2.2.5.2 Maturity schedule**

Maturity parameters in this update assessment were carried over from 2015 benchmark and 2019 update assessments. Please refer to Hicks and Wetzel (2015) for further details.

#### **2.2.5.3 Fecundity**

Fecundity parameters remain unchanged from previous assessment. Please refer to Hicks and Wetzel (2015) for further details.

#### **2.2.5.4 Natural Mortality**

In this assessment, natural mortality ( $M$ ) is estimated for females and males, while using the Hamel and Cope (2022) prior. The prior on  $M$  has been updated to reflect the most recent guidance from Hamel and Cope (2022); the log-mean therefore remains unchanged while the log-SD has been set to 0.31. Using a maximum age of 54 the point estimate and median of the prior on  $M$  is 0.10.

#### **2.2.5.5 Length-at-age**

Growth parameters were fully estimated within the assessment model, for females and males separately following the same formulation in 2015 and 2019 assessment models.

#### **2.2.5.6 Ageing bias and imprecision**

Ageing error matrices were unchanged from the previous assessment. Please refer to Hicks and Wetzel (2015) for details.

### **2.3 Environmental and Ecosystem Data**

This assessment did not use any environmental or ecosystem data related to the stock.

### 3 Assessment model

#### 3.1 History of modeling approaches

This section is not required for an update assessment; please refer to the most recent full assessment (Adams et al. 2019) for additional information.

#### 3.2 Responses to most recent past STAR Panel recommendations

This section is not required for update assessments.

#### 3.3 Responses to SSC Groundfish Subcommittee requests

To be completed after SSC GFSC review.

#### 3.4 Model Structure and Assumptions

##### 3.4.1 Model Changes from the Last Assessment

The assessment followed the same model structure as the 2015 base assessment (Hicks and Wetzel 2015) and 2019 update assessment (Adams et al. 2019). The changes made to the previous assessment model include:

- **Adding most recent data from commercial fleets** (as described in Data section of this report).
- **Updating WCGBTS index using current methodology** (as described in Data section of this report).
- **Updating the prior for natural mortality** based on Hamel and Cope (2022).
- **Updating length-weight parameters estimated** while including most recent data.
- **Extending the main period for estimating recruitment deviations and updating recruitment bias adjustment parameters** based on Methot and Taylor (2011).
- **Adding a block to the retention curve for the midwater trawl fleet and a block to hake fleet selectivity to account for recent changes in fleet behavior.** Adding a block to the retention curve for midwater trawl allowed for

recent increases in midwater trawl discards (from 2017 forward), and improved fit to discard amounts modeled in the assessment. Adding a block to hake fleet selectivity accounted for a change in fish mean length (2020-2024) due to shifts in the spatial distribution of the hake fleet and to improve fit to length compositions. Neither change had a discernible influence on the estimated SSB. See Model Bridging section for detail.

- **Adding hook-and-line discards to landings in the hook-and-line fleet.** The change to the treatment of hook-and-line discard was necessary since discard lengths for the hook-and-line fleet provided by WCGOP this year were corrected to omit nearshore fixed gear fleets samples, which were erroneously included with the hook-and-line fleet in the previous benchmark and update assessments. This change resulted in changes to the discard length distribution and years for which data was available (Figure 19). With decreased sample sizes of hook-and-line discard length data available, the model was unable to reliably estimate retention parameters and exhibited substantial sensitivity to even slight changes in discard amounts within the hook-and-line fleet. Therefore, in this assessment, we added the hook-and-line discard to hook-and-line landings. Correction of the hook-and-line discard lengths translated into lower estimated recruitment in the 2010s than that of in 2019 model (higher recruitment estimates in the 2019 assessment were previously informed by erroneous estimates of smaller fish, which were corrected in this assessment). Lower recruitment in turn caused a decrease in stock size in recent years.

#### 3.4.1.1 Model Bridging

The exploration of models began by bridging from the 2019 update assessment to SS3 version 3.30.2, which produced no discernible difference. We then focused on data bridging. Updating the catch series did not have a substantial effect on the historical biomass, and estimated the stock biomass increasing from 2000 to 2020 before decreasing up to the current period. Updating the model discards had the most significant impact on the absolute stock biomass (SSB), with a small decrease in absolute SSB prior to 1980 and a large decrease in absolute SSB from the mid 2010s through the current year (Figure 24). Updating model indices had a similar effect, while updating the age and length composition data increased the absolute stock biomass in the current period. Updates to discards likewise had the largest effect on relative SSB (fraction of unfished biomass); changes in relative SSB owing to all other datasets were in general small.

None of the other model bridging steps had a substantial effect on the estimates of stock biomass (Figure 24). The model bridging changes included (1) updating the prior for natural mortality ( $M$ ) to follow that recommended by Hamel and Cope (2022), (2) updating fixed parameters of the male and female length-weight curve by fitting to data from the WCGBTS, ASHOP, and the triennial survey outside the model, (3) re-fitting the bias adjustment ramp for recruitment deviates, (4) adding a block on retention in

the midwater trawl fishery from 2011-2016 and allowing estimation of retention in the final years of the model, which was previously fixed at 0.99, (5) adding a block to hake fleet selectivity from 2020-2024 (5) re-fitting the model using the MLE as initial values following a jittering analysis which revealed the previous MLE was a local minima. These changes collectively resulted in a very small decrease in relative SSB post-1990, and pairwise correlations among all shared parameters in these models were high ( $>0.999$ ). Bridging from the previous prior on M to the Hamel and Cope (2022) prior is detailed in the “priors” section.

To estimate discards in the model, time blocks for changes in selectivity and retention in discard data were used. Except for the aforementioned addition of blocks to the midwater trawl and hake fleets, the same structure for time blocks was used as in the previous assessment (Adams et al. 2019). The addition of midwater trawl and hake fleets block was necessitated by poor fits to midwater trawl discards and the length composition data from the hake fleet in from 2020 - 2024, respectively. The poor fit to hake fleet length composition data may be due to the high variability in the distribution of the hake / pacific whiting fleet between years, as the fleet moves to avoid bycatch (Holland and Martin 2019). Poor fit to midwater trawl discards is thought to be due to (1) the previous decision to fix late-year retention to 0.99 which represented an overestimate of the (very low) discards in 2011-2016, and (2) the reallocation of quota shares and subsequent increase in midwater trawl discards in 2017. These choices are described in more detail in the “fits to data” section.

#### **3.4.2 Modeling Platform and Structure**

For this update assessment, new versions of the previously used software were used. Stock Synthesis v3.30.13 was used to estimate the parameters in the 2019 model. R4SS, version 1.35.3, along with R version 3.5.3 were used to investigate and plot the 2019 model fits. For the update, Stock Synthesis v3.30.2 and R4SS, version 1.51.0, along with R version 4.5.0 were used. A summary of the data sources used in the model (details discussed above) is shown in Figure 23.

#### **3.4.3 Model Overview**

The model is a two-sex, age-structured model starting in 1916 with an accumulated age group at 40 years. Sex-specific growth and natural mortality were estimated. The lengths in the population were tracked by 1 cm intervals and the length data were binned into 2 cm intervals. A curvilinear ageing imprecision relationship was estimated and used to model ageing error. Fecundity was assumed to be proportional to body weight, thus spawning biomass was used as the measure of spawning output.

### 3.4.3.1 Model Fleets and Areas

The assessment uses a single-area model, consistent with previous assessments (Adams et al. 2019). Multiple fisheries encounter widow rockfish. The definitions of fishing fleets have not been changed from previous assessments (Adams et al. 2019).

### 3.4.4 Model Parameters

#### 3.4.4.1 Estimated and Fixed Parameters

There were 214 estimated parameters in the base model. These included one parameter for recruitment ( $R_0$ ), 10 sex-specific parameters for growth, two sex-specific natural mortality parameters, four parameters for extra variability on the survey indices (survey indices were fixed at zero), four parameters for the catchability of the hake series and the Triennial Shelf survey (the catchabilities for other surveys were calculated analytically), 49 parameters for selectivity, retention, and time blocking of the fleets, eight parameters for survey selectivity, 125 recruitment deviations, and 12 forecast recruitment deviations.

Fixed parameters in the model were as follows. Consistent with (Adams et al. 2019), steepness was fixed at 0.72 as was the mean of the current west coast rockfish steepness prior as described above. A sensitivity analysis and a likelihood profile were done for steepness. The standard deviation of recruitment deviates was fixed at 0.60. Maturity at age was fixed as described in (Adams et al. 2019). Length-weight parameters were fixed at estimates using length-weight observations from the WCGBTS (Figure 20 and Table 13).

The final base model assumed asymptotic selectivity (using the double-normal formulation in SS3) for each fishery, except for the midwater trawl fishery. The NWFSC and Triennial surveys both used spline curves. All selectivity curves were length based and the same shape as the 2019 update, with the exception of the NWFSC survey fleet. The NWFSC survey fleet selectivity was estimated to be slightly lower at lengths greater than 45 cm, compared to the selectivity estimated in 2019.

Time blocks were used for selectivity and retention parameters in the bottom trawl, midwater trawl, hake and hook-and-line fisheries as indicated in Table 12.

#### 3.4.4.2 Priors

The prior on natural mortality ( $M$ ) in the previous assessment was defined as a lognormal with mean on the log-scale of  $\ln(5.4/\text{Amax})$  and  $\text{SD}(\ln(M)) = 0.4384343$  following

analysis of the data in (Then et al. 2015) by Owen Hamel and the authors. In the current assessment the prior on M has been updated to reflect guidance from (Hamel and Cope 2022); the log-mean therefore remains unchanged while the log-SD has been set to 0.31. Using a maximum age of 54 the point estimate and median of the prior on M is 0.10.

The prior for steepness ( $h$ ) assumes a beta distribution with parameters based on an update of the Dorn rockfish prior (commonly used in past West Coast rockfish assessments) conducted by Jim Thorson (pers. comm, NWFSC, NOAA) which was reviewed and endorsed by the SSC in 2015. During the stock assessment review, it was decided that the steepness prior should be developed without the past widow Rockfish data to avoid using the same data to inform both the model prior and likelihood. Without widow rockfish, the prior used for the 2015 assessment was a beta distribution with mean = 0.798 and SD = 0.132 (corresponding beta parameters  $\alpha = 6.59$  and  $\beta = 1.667$ ). The 2019 update assessments used the current West Coast rockfish steepness prior with mean = 0.72 and SD = 0.16 ( $\alpha = 4.95$ ,  $\beta = 1.93$ ) which was approved for use in all rockfish stock assessments for 2019. This update assessment uses the same prior.

#### **3.4.4.3 Recruitment deviations**

The specification of when to estimate recruitment deviations is an assumption that likely affects model uncertainty. Recruitment deviations from 1900–2024 were estimated to appropriately quantify uncertainty. The earliest length-composition data occur in 1976 and the earliest age data were in 1978. The most informed years for estimating recruitment deviations based on available composition data were from about the mid-1970s to about 2019. The period from 1900–1970 was fit using an early series with little or no bias adjustment, the main period of recruitment deviates was 1971–2020 with an upward and downward ramping of bias adjustment, and 2021 onward was fit using forecast recruitment deviates with little bias adjustment. (Methot and Taylor 2011) summarize the reasoning behind varying levels of bias adjustment based on the information available to estimate the deviates. The standard deviation of recruitment variability (sigma- R) was assumed to be 0.6 in the 2015 assessment, based on iteratively tuning to a value slightly less than the observed variability of recruitment deviations in the period 1975–2010 in 2015 (Figure 34).

#### **3.4.4.4 Sample weights**

As previous full assessment used the McAllister & Ianelli method (Hicks and Wetzel 2015) and changing the weighting method is outside the TORs for an update, Francis weighting method is presented as a sensitivity.

The 2019 update assessment weighted composition data via the lambdas (Adams et al. 2019). In the current assessment, the method to weight the composition datasets in SS3

was to use variance adjustment factors as the weighting factors. The fleet and data-type (length or age) factor was entered as variance adjustments factors until the harmonic mean of the effective sample sizes matched the mean of the adjusted input sample sizes (McAllister and Ianelli 1997). Once the weighting was determined, lambda factors for all fleets with both marginal length and marginal age compositions were down-weighted by 0.5 to account for the potential double use of data since length and age are observed from the same fish.

#### 3.4.5 Key Assumptions and Structural Choices

This section is not required for an update assessment; please refer to the most recent full assessment (Hicks and Wetzel 2015) for additional information.

### 3.5 Base Model Results

As a supplement to the model results figures included in this report and described below, a full set of [diagnostic plots](#) created by the r4ss package (Taylor et al. (2021)) is available on the assessment GitHub repository ([github.com/mcgoodman/widow-assessment-update](https://github.com/mcgoodman/widow-assessment-update)) along with the Stock Synthesis [input files](#).

#### 3.5.1 Parameter Estimates

The base model parameter estimates along with approximate asymptotic standard errors are shown in Table 13 and the likelihood components are shown in Table 14. Estimates of key derived parameters and approximate 95% asymptotic confidence intervals are shown in Table 15.

The estimates of natural mortality ( $0.124511 \text{ yr}^{-1}$  and  $0.136682 \text{ yr}^{-1}$  for females and males, respectively) were higher than suggested by the medians of the prior distributions used in this assessment and the 2015 assessment. Fixing M at lower values than those estimates resulted in a pattern of reduced recruitment immediately before the fishery started. This suggests that the model is attempting to reduce the number of observations of older fish in the data. The estimates of M fall within the 95% confidence interval of the prior distribution (0.055–0.184), and are shown in Figure 22.

Estimating M is difficult in stock assessments, and the estimated values may represent model misspecification instead of the actual life-history trait. However, in alternative models to the base, the estimates of M were rarely less than  $0.14 \text{ yr}^{-1}$  (Table 17).

Uncertainty in the estimated M was also much less than the range of the prior (Figure 22). The assumption that appeared to have the largest effect on M was introducing dome-shaped selectivity in the midwater trawl fleet, which made M smaller (Table 17).

Selectivity curves were estimated for commercial and survey fleets and parameter estimates are provided in Table 13. The estimated selectivity, retention, and keep (the product of selectivity and retention) curves for the trawl and hook-and-line fleets are shown in Figure 25. The selectivity curves showed a shift to larger fish in 2002 for the bottom trawl fishery and a shift to smaller fish in 2003 for the hook-and-line fishery. The bottom trawl shift is consistent with the introduction of the Rockfish Conservation Area (RCA) and gear restrictions (shoreward of the 18 RCA) that virtually eliminated fishing in shelf habitats where smaller widow rockfish would more likely be encountered. Around this same time, the fixed-gear RCA specifications began preventing fishing between 30 and 100 m. Due to it consistently approaching the lower bound when estimated, the decision was made to fix the log-ascending width of the hook-and-line fleet selectivity curve at -5.

The retention curves (Figure 43) showed a shift to retaining a lower percentage of fish since trip limits were introduced. The asymptote of the retention curve for the bottom trawl fishery sequentially decreased as more management restrictions were introduced to about 50% retention of larger fish in the 1998–2010 period. In recent years, bottom trawl retention is estimated at approximately 99%.

Midwater trawl and hook-and-line fisheries estimated an asymptote to retention just above 80% for the period 1983–2010. Both the selectivity for the hake fleet and the selectivity of the net fleet did not support dome-shaped selectivity (Figure 25). The estimated selectivity curves for the Triennial and WCGBTS were similar to each other except that the triennial survey selected larger fish (Figure 26). The WCGBTS exhibited a more pronounced dome-shaped selectivity compared to the 2015 assessment.

In the 2015 assessment, additional survey variability (process error added directly to each year's input variability) for the triennial and WCGBTS was not estimated in the model because the estimate was zero (Hicks and Wetzel 2015). To avoid bound issues in estimation of the Hessian, the authors fixed these at zero because the model results included reasonable estimates of variance. We retained the same modelling approach for the update assessment. The additional standard deviation added to the fishery-dependent indices was quite large, ranging from 0.16 for the bottom trawl index and 0.58 for the foreign at-sea hake fleet. The additional variability on the juvenile survey was the highest, at 1.68, giving the index very little weight in the model.

The estimates of maximum size for both females and males (Table 13) did not differ substantially from Adams et al. (2019). Estimates of k were slightly different in the model, but that is expected when accounting for selectivity. Estimated growth curves are shown in (Figure 32).

Estimates of recruitment suggest that the widow rockfish population is characterized by variable recruitment with occasional strong recruitment events and periods of low recruitment (Figure 33, Table 15). There is little information regarding recruitment prior to 1965.

### 3.5.2 Fits to the Data

Fits to data are discussed for survey abundance indices, discard data (biomass and length compositions), length composition data for the fisheries and surveys, marginal age compositions for the fisheries, and conditional age-at-length observations for the WCGBTS.

Survey indices and total discards were fitted assuming a lognormal likelihood. The five indices of abundance (three survey series, and two fishery indices of abundance) are shown in Figure 35. The Triennial Shelf Survey treatment was consistent with (Adams et al. 2019). Extra standard error was estimated for all of the series except for the two survey series (Table 13). None of the series showed patterns in residuals, and with the large amount of error, none of the series showed serious lack of fit. The recent WCGBTS showed a general increase from 2003 - 2015 followed by a general decrease from 2016 - 2024, which was also estimated in the base model (Figure 35, middle right). Low (2015, 2021, 2022) and high (2016) estimates of abundance did not fit well in the model.

The 2019 model applied four time blocks to midwater trawl retention, with constant fixed discard rates of 1% in both early years (1916-1981) and late years (2011 onward). With the addition of new discard data since the 2017 reallocation, the use of a fixed discard rate from 2011 onward resulted in poor fits to the discard data. Therefore the current assessment utilizes an additional block on retention from 2011-2016, with the final block beginning in 2017; retention is estimated in both the 2011-2016 and 2017-2024 time blocks, though it remains fixed for the earliest time block (1916-1981) at the value used in the previous assessment. The first time block with discard data was 1983 to 2001. Predicted discards for all three years of the Pikitch data (1985–1987) were underfit, but within the confidence limits (Figure 36). EDCP data in 1997 and 1998 were underfit. The second time block was from 2002-2010, which contained only one observation in 2002 (and was fit exactly, as expected). Discard rates were overestimated in 2012-2013 and underestimated in 2015-2016, though they were generally well fit in in the 2017-2024 time blocks.

Fits to the length-composition data are displayed in two different ways: the Pearson residuals-at-length are shown for each year for all types of length compositions, and also compared across fleets. More detailed plots of fitted lines drawn over the plotted proportions at length are shown in Appendix A. Pearson residuals for the fisheries (Figure 37, Figure 38) do not show consistent patterns, but they do show that some fleets

are not fitting some cohorts. Each fleet also shows that there are periods where older fish are underfit, and periods when older fish are overfit. With a peaked length frequency distribution, it is common for these patterns to appear given shifts in the expected distribution due to sampling error, and time-varying parameters that are assumed time-invariant. The net fishery observed some very large fish in the first two years of data, but did not observe those fish in later years. This pattern was not seen in any other fishery. There were also years where females showed positive residuals (filled circle, observed > expected) and males showed negative residuals (e.g., Figure 37, early years of bottom trawl and midwater trawl). It is uncertain if this pattern is related to growth, sexing error, or to sex-specific selectivity (e.g., when widow rockfish aggregate, sexes possibly may be aggregating separately). Overall, the fits to commercial fishery length compositions showed some patterns that the 2015 assessment deemed to require complicated modelling assumptions to alleviate. However, the residuals were mostly less than 2 in absolute value, especially for fleets that were well informed by data. The model fits the marginal length composition integrated among years for each fleet well (Figure 39).

The fits to bottom trawl discard length frequencies were generally good except in the years since trawl rationalisation began (2011). These recent years observed small fish, which the estimated selectivity of the trawl fleet did not allow for. There were no other years that showed small fish being caught by the trawl fleet. Attempting to explain these small fish with additional time blocks on selectivity and retention did not help because explaining the small fish in the discards worsened the fits to the landed and larger fish. Discards are extremely small in this time period, so it is unlikely that a misfit here will have a lot of effect on the model. Combining the discard length frequencies over years may not be appropriate for the bottom trawl fishery due to the likely changes in discarding practices, but Figure 37 shows the prediction of discarding smaller females than observed and a more peaked observed distribution of discarded males than predicted.

The Triennial Shelf and WCGBTS surveys length frequencies showed underfitting of older fish in some years and underfitting of younger fish in others (Figure 40). The combined length frequencies across years were bimodal with a valley around 37 cm, and the model showed an indication of a bimodal distribution but was unable to adequately capture both peaks (Figure 39). The nonparametric selectivity pattern helped to reduce this pattern, but selectivity may be even more complicated for the surveys.

Age data were fitted as marginal age compositions for the fishing fleets and as conditional age-at-length for the WCGBTS, which were expanded by tow and then by strata. Raw observations of age-at-length, which assumes that within each length bin the observed ages are a random sample of fish, were not used as they are inconsistent with the length compositions which are expanded. Using expanded age-at-length ensures that as the length bin size is increased, it approaches the expanded marginal age composition. Pearson residuals for the commercial fleets are shown in Figure 37 and Figure 38. For the trawl fisheries in Figure 37, there are diagonal patterns that mostly correspond to cohorts ageing through the years. However, there are instances where the diagonal seems

to shift, such as the filled circles of the midwater trawl fishery on the lower left of the plot (years 1981–1991). The patterns match the length compositions residuals in some cases. The bottom trawl fishery shows the largest residuals in the most recent years, which could indicate a change in selectivity. The net and hook-and-line fits to age compositions (Figure 38) showed larger residuals than the trawl fisheries. As with the fits to the length compositions, the net fishery showed the inability to match the large number of older fish observed in the early years. There appears to be a strong shift in residuals in 1988 when a lack of fit to potentially a cohort appears. The residuals were typically less than 2 for fits to the age data. However, the female age compositions occasionally produced some large residuals that were not consistently seen in the male age compositions. Aggregating across years shows that the fit to age comps was good for the trawl fleets and less so for the net and hook-and-line fleets, which had smaller sample sizes (Figure 41). The aggregated data also showed that the predictions were often unable to fit the peak in the data.

The observed and expected age-at-length are shown in Figure 42 for the twelve years of the WCGBTS observations. The fits generally match the observations with some misfit at larger lengths. The standard deviation of age-at-length was variable and often the expectation was higher than the observations at larger lengths. Plots with the residuals for individual observations showed reasonably good fits to the conditional age-at-length data from the NWFSC shelf/combo survey (Figure 44). Some outliers are apparent, with large residuals mostly at smaller lengths for a given age.

### 3.5.3 Population Trajectory

The predicted spawning biomass (in metric tons) is given in Table 16 and plotted in Figure 45. The predicted spawning biomass from the base model generally showed a slight decline over the time series until 1966 when the foreign fleet began. A short, but sharp decline occurred, followed by a steep increase due to strong recruitment. The spawning biomass declined rapidly with the developing domestic midwater fishery in the late 1970s and early 1980s. The stock continued to decline until 2000 when a combination of strong recruitment and low catches resulted in a quick increase from 2000 - 2018. The stock declined rapidly from 2019 until the end of the time series, due to a combination of increased catches and low recruitment.

The 2025 spawning biomass relative to unfished equilibrium spawning biomass is above the target of 40% of unfinished spawning biomass (49.3%), with a low of 33.9% in 2001 (Figure 47). This suggests that widow rockfish was not overfished, as was inferred from previous assessments (Williams et al. 2000). Approximate confidence intervals based on the asymptotic variance estimates show that the uncertainty in the estimated spawning biomass is high, especially in the early years. It should be noted that while the stock

is currently above the 40% target, the target does fall within the approximate 95% confidence interval (Figure 47).

Recruitment deviations (Figure 33 and discussed in Section 3.3.1) provide a more realistic portrayal of uncertainty. There are very large, but uncertain, estimates of recruitment in 1970, 2008, 2016, and 1971 (in descending order of magnitude). Other large recruitment events (in descending order of magnitude) occurred in 1978, 1981, 2010, 1991, and 1997. The five lowest recruitments (in ascending order) occurred in 2012, 2019, 2020, 2011, and 1976. The 2008 and 2016 year classes were estimated as 2 of the 4 strongest year classes. The 2019 update assessment estimated the 2013 recruitment as the strongest year class over the duration of the fishery, however the current assessment does not support this. It may be worthwhile to investigate the periods of strong and weak year classes further to see if it is an artifact of the data, a consistent autocorrelation, or a result of the environment. The input bias adjustment ramp matched the estimated (Figure 34).

The stock-recruit curve resulting from a fixed value of steepness is shown in Figure 34 with estimated recruitments also shown. The stock is predicted to have never fallen to low enough levels that the steepness is obvious. However, the lowest levels of predicted spawning biomass showed some of the smallest recruitments and very few above average recruitments. Steepness was not estimated in this model, but sensitivities to alternative values of steepness are discussed below.

## 3.6 Model Diagnostics

### 3.6.1 Convergence

Model convergence was determined by examining the final gradient, checking that the Hessian was positive (semi-)definite, and initializing the minimizer from perturbed values around the maximum likelihood estimates (MLE) to determine if the model found a better minimum (“jittering”). Initial jittering analyses indicated that the model had converged to a false (local) minimum, though the difference in log-likelihoods at the previous estimates and the new MLE was small (<0.5). After accepting the new MLE as the base model, jittering was repeated 100 times with a jitter coefficient of 0.10 and (using a convergence threshold of 0.01) a better minimum was not found. 2% of the jittered models achieved the minimum negative log-likelihood and 18% were within two likelihood units. Through the jittering done as explained above and likelihood profiles, we are confident that the base case as presented represents the best fit to the data given the assumptions made. There were no difficulties in inverting the Hessian to obtain the parameter variance-covariance matrix. Likelihood profile runs which fixed M, R<sub>0</sub> and h at more extreme values did not initially converge. This was addressed by using the parameter estimates from models with less extreme values as starting values in subsequent

models. Convergence was defined as the lowest negative log-likelihood achieved with jittering where the Hessian matrix was invertible.

### 3.6.2 Parameter Uncertainty

Parameter estimates are shown in Table 13 and Table 16 along with approximate asymptotic standard errors. The only parameters with an absolute value of correlation greater than 0.95 were the female and male natural mortality parameters, which is expected. Estimates of key derived quantities are given in Table 15 along with approximate 95% asymptotic confidence intervals. There is a reasonable amount of uncertainty in the estimates of biomass. The confidence interval of the 2025 estimate of depletion is 30.12%–69.17% and above the management target of 40% of the unfished spawning biomass.

### 3.6.3 Sensitivity Analyses

Sensitivity analysis was performed to determine the model behavior under different assumptions than those of the base case model. 8 sensitivity analyses were conducted to explore the potential differences in model structure and assumptions, including:

1. Fixed natural mortality at 0.1 for both sexes (2015 assessment prior)
2. Fixed natural mortality at  $0.124 \text{ yr}^{-1}$  for females and  $0.129 \text{ yr}^{-1}$  for males (2011 assessment prior)
3. Forcing asymptotic selectivity on the midwater trawl fleet
4. Fitting logistic curves for WCGBTS selectivities
5. Weighting the composition data using the Francis method
6. Updated Washington catch reconstruction
7. Inclusion of previously excluded shrimp trawl data
8. Exclusion of triennial survey data

Likelihood values and estimates of key parameters are shown in Table 17. Predicted spawning biomass trajectories, estimated recruitment deviations and comparisons of model estimates for 2025 are shown in Figure 52, Figure 53 and Figure 54. The estimates of current stock depletion ranged from 9.29%–155.29% across the sensitivity runs, with including previously excluded shrimp trawls resulting in the lowest estimate and forcing asymptotic selectivity on the midwater trawl fleet resulting in the highest estimate. Generally, the trajectory of the spawning biomass was qualitatively similar across all tested models, e.g., peak around late 1970s and late 2010s, projected decrease in biomass in 2025 followed by some recovery into the 2030s; the quantitative magnitude of these trends did vary across cases.

Fixing M at values lower than the base case estimate resulted in decreases in estimated spawning biomass, while fixing steepness across the values tested resulted in similar or increased estimated spawning biomass. The relative spawning biomass in 2025 changed to 86.75% with an M of  $0.124 \text{ yr}^{-1}$  and  $0.129 \text{ yr}^{-1}$  for females and males, respectively (2011 assessment prior), and to 49.11% with an M of  $0.1 \text{ yr}^{-1}$  (2015 assessment prior).

Forcing asymptotic selectivity on the midwater fleet increased estimated biomass in 2025 by 155.29% compared to base model, while forcing logistic selectivity on the NWFSC WCGBT resulted in similar estimated spawning biomass to the base model. Including shrimp trawl data and updating WA catch reconstruction had almost no impact on the estimated spawning biomass. Excluding the triennial survey data lead to slight increases in estimated spawning biomass.

The alternative weighting using the Francis method generally increased the estimate of spawning biomass across the timeseries, but the estimated biomass for 2025 was similar between the Francis weighted model and the base model (130.59% compared to base model).

#### **3.6.4 Retrospective Analysis**

A 5-year retrospective analysis was conducted by running the model using data only through 2020, 2021, 2022, 2023, and 2024 progressively (Figure 55). The initial scale of the spawning population was basically unchanged for all of these retrospectives. Removing 4–5 years of data led to slightly lower estimates of fishing mortality (F) and slightly higher spawning biomass over the last 15 years. In contrast, removing only 1–2 years resulted in higher F and lower biomass estimates. Despite these minor differences, population trends from all retrospective runs were very close, and there were no consistent patterns as years were removed. No concerning patterns were observed in the retrospective analysis.

#### **3.6.5 Likelihood Profiles and key parameters**

Likelihood profiles were conducted for R<sub>0</sub>, steepness (even though it was not estimated in the base case) and over male and female natural mortality values simultaneously. These likelihood profiles were conducted by fixing the parameter at specific values and removing the prior on the parameter being profiled. Without the original prior distribution the MLE estimates from the base case will likely be different than the MLE in the likelihood profile, but this displays what information the data have. There was some difficulty in achieving model convergence for many parameterizations in the likelihood profile. In some cases jittering was required.

For profiles of natural mortality, the negative log-likelihood was minimized at a value of 0.132 for males, and a value of 0.121 for females. Profiles for natural mortality for each sex are illustrated in (Figure 58). For steepness, the negative log-likelihood was minimized at a steepness of 0.825, but the 95% confidence interval extends over the entire range of possible steepness values. Profiles for steepness are illustrated in (Figure 57). For R<sub>0</sub>, the total likelihood supported the estimated value, though there was variable support for each likelihood component across the range of R<sub>0</sub> evaluated. As R<sub>0</sub> increased, natural mortality also increased and the relative spawning biomass in 2024 was less depleted. Profiles for R<sub>0</sub> are illustrated in Figure 56.

## 4 Management

### 4.1 Reference Points

Reference points were calculated using the estimated selectivities and catch distribution among fleets in the most recent year of the model (2024). Sustainable total yields (landings plus discards) were 5,594 mt when using an SPR50% reference harvest rate and with a 95% confidence interval of 5,594 to 5,594 mt. The spawning biomass equivalent to 40% of the unfished spawning output (SB40%) was 32,592 mt. Catches between the late 1990's and 2016 were well below the point estimate of potential long-term yields calculated using an SPR50% reference point, and the population is estimated to have increased continuously throughout that time period. However, catches from 2017 through 2024 were above the point estimate of potential long-term yields using an SPR50% reference point, exceeding the upper bound of the confidence interval in all years since 2018, and exceeding the point estimate by on average 83%.

The predicted spawning biomass from the base model generally showed a slight decline until the late 1970s, followed by steep increase above unfished equilibrium biomass and reaching a peak in 1979. This was followed by a steep decrease up to the mid-1980s, and then a more gradual decrease through 2000 (Figure 47). Between 2001 and 2016, the spawning biomass increased continuously due to small catches, and several years of high recruitment (though with lower than average recruitment in other recent years). The spawning biomass relative to unfished equilibrium spawning biomass climbed above the target of 40% of unfished spawning biomass in the early 2000's. It is estimated to still be above the target, though the lower bound of the 95% confidence interval lies between the target and minimum stock size threshold (Figure 47). The fishing intensity (relative 1-SPR) exceeded the current estimates of the harvest rate limit (SPR50%) throughout the 1980s and early 1990s, and has again since 2018 (Figure 50). Exploitation rates on widow rockfish between 2001 and 2016 were predicted to be far below target levels. In recent years, the stock has experienced exploitation rates that have been above the target level while the biomass level has remained above the target level (Figure 51).

The equilibrium yield plot is shown in Figure 60, based on a steepness value fixed at 0.720. The predicted maximum sustainable yield under the assumptions of this assessment occurs near 25% of equilibrium unfished spawning biomass.

### 4.2 Unresolved problems and major uncertainties

Major sources of uncertainty include landings, discards, natural mortality, and recruitment, which are discussed below.

Because widow rockfish is a marketable species, historical discard rates were likely lower than less desirable or smaller species. This assessment assumed that discarding was nearly negligible before management restrictions began in 1982. Once trip limits were introduced, discarding tended to be an all or none event, and detecting large, but rare, discard events with far less than 100% observer coverage has a low probability. From 2002 onward, the WCGOP has provided data on discards from vessels that were randomly selected for observer coverage, thus some uncertainty is present in the total amount discarded. The implementation of trawl rationalization in 2011 resulted in almost 100% observer coverage for the trawl fleet and very little incentive to discard widow rockfish. The open access fixed-gear fleet is not monitored by the full observer coverage required under trawl rationalization. Discard mortality is assumed to be 100%, which may overestimate actual mortality (Jarvis & Lowe, 2007), but given the low number of discards, is likely to have a minimal effect on assessment results.

There may also be uncertainty in the ability of bottom trawl surveys to be a reliable measure of widow abundance, which spend a significant portion of their time in mid-water (Wilkins 1986). Multiple surveys are used in the assessment, but further consideration of additional surveys is reasonable.

Widow rockfish is a relatively long-lived fish, and natural mortality is likely to be lower than many species of fish, such as gadoids. Ages above 50 years have been observed and it is expected that natural mortality could be less than  $0.10 \text{ yr}^{-1}$  (the median of the prior for natural mortality used in this assessment). However, even with length and age data available back to the late 1970s, natural mortality was estimated at 0.125 for females and  $0.137 \text{ yr}^{-1}$  for males, with a small amount of uncertainty (e.g., a 6.6% coefficient of variation for females). This assessment attempts to capture that uncertainty by estimating natural mortality ( $M$ ) and integrating that uncertainty into the derived biomass estimates, as well as additional uncertainty by including levels outside of the predicted interval in a decision table.

Model sensitivities and profiles over  $M$  showed that current stock status was highly sensitive to the assumption about natural mortality. Notably, the estimated natural mortality values for both sexes from this assessment are lower than those from the 2015 and 2019 assessments, for which natural mortality was estimated above  $0.15 \text{ yr}^{-1}$  and  $0.14 \text{ yr}^{-1}$ , respectively. The estimates of  $M$  varied slightly depending on the weight given to age and length data, or removing recent years of data, but  $M$  was always estimated above  $0.12 \text{ yr}^{-1}$ . The likelihood profile over natural mortality provides support for values up to or above  $0.14 \text{ yr}^{-1}$ , but with greater curvature than in the 2019 assessment, suggesting additional data has reduced the support for higher natural mortality values.

Steepness was fixed at 0.720 in the base model, but a likelihood profile showed that it would be estimated at a value less than that. Estimates of  $M$  increased with lower steepness, while unfished equilibrium spawning biomass increased and current spawning

biomass decreased. Sustainable yields at the SPR50% reference harvest rate ranged from approximately 2641 to 5992 mt depending on the value of steepness.

#### 4.3 Harvest Projections and Decision Tables

Two categories of parameters that greatly contributed to uncertainty in the results were natural mortality (an important estimated parameter) and steepness (not estimated in the model). A combination of these two factors was used as the axis of uncertainty to define low and high states of nature. This differed from the 109 assessment which included a third factor, 2013 recruitment strength. The 12.5% and 87.5% quantiles for female and male natural mortality (independently) were chosen as low and high values ( $0.115 \text{ yr}^{-1}$  and  $0.134 \text{ yr}^{-1}$  for females;  $0.127 \text{ yr}^{-1}$  and  $0.146 \text{ yr}^{-1}$  for males). Steepness is probably the most important factor since it was fixed in the base model and is not incorporated in the estimation uncertainty. The 12.5% and 87.5% quantiles from the steepness prior (without widow rockfish data) were used to define the low and high values of steepness (0.536 and 0.904). The low combination of these three factors defined the low state of nature and the high combination of these three factors defined the high state of nature. The predictions of spawning biomass in 2025 from the low and high states of nature are close to the 12.5% and 87.5% lognormal quantiles from the base model.

A twelve year projection of the base model with two catch streams based on ACL adjustments of 0.45 P\* and 0.25 P\* were conducted (Table 20).

Projections with catches based on the predicted annual catch limit (ACL) using the SPR rate of 50%, the 40:10 control rule, and a 0.45 P\* adjustment using a sigma of 0.50 from 2027 onward suggest that the spawning biomass will decrease over the projection period for all states of nature. Predicted ACL catches range from 3,321 mt in 2027 to 4,392 mt in 2036 Table 20, Figure 61).

Projections with catches based on the predicted annual catch limit (ACL) using the SPR rate of 50%, the 40:10 control rule, and a 0.25 P\* adjustment using a sigma of 0.50 from 2027 onward suggest that the spawning biomass will decrease over the projection period for all states of nature. Predicted ACL catches range from 1,790 mt in 2027 to 1,886 mt in 2036 Table 20, Figure 61).

This assessment synthesizes many sources of data and estimates recruitment variability, thus it is classified as a Category 1 stock assessment. Therefore, the sigma for P\* to determine the catch reduction to account for scientific uncertainty is 0.50.

#### **4.4 Evaluation of Scientific Uncertainty**

Spawning biomass is estimated to be at 40,603 mt in 2025, with a sigma of 0.2753. OFL is estimated to be 5,667.1 mt in 2019 with a coefficient of variation of 0.3187.

#### **4.5 Regional management considerations**

Widow rockfish are managed on a coastwide basis and observed more often in the WCGBTS north of latitude 40° 10' N. Bottom trawl catches in California have historically been as large as in Oregon and larger than in Washington, but recently catches in California have been small. Future assessments and management of widow rockfish may want to monitor where catches are being taken to make sure that specific areas are not being overexploited. In addition, research on the connectivity along the coast as well as regional differences would help to inform the potential for overfishing specific areas.

#### **4.6 Research and Data Needs**

There are many areas of research that could be improved to benefit the understanding and assessment of widow rockfish:

- **Historical landings and discards:** Although progress has been made in reconstructing historical landings of rockfish on the U.S. West Coast, the historical landings and discards continue to be uncertain for widow rockfish and improvements would increase the certainty that fishing removals are applied appropriately. Because landings are assumed to be known exactly in the assessment model, uncertainty in the predictions does not include uncertainty in the landings. A thorough look at historical landings, species compositions, and discarding practices would reduce the potential uncertainty that is not entirely accounted for.
- **Natural mortality:** Uncertainty in natural mortality translates into uncertain estimates of status and sustainable fishing levels for widow rockfish. The collection of additional age data, re-reading of older age samples, reading old age samples that are unread, and improved understanding of the life-history of widow rockfish may reduce that uncertainty.
- **Coastwide understanding of stock structure, biology, connectivity, and distribution:** This is a stock assessment for widow rockfish off of the west coast of the U.S. and does not consider data from British Columbia or Alaska. Further investigating and comparing the data and predictions from British Columbia and

Alaska to determine if there are similarities with the U.S. West Coast observations would help to define the connectivity between widow rockfish north and south of the U.S.-Canada border.

## 5 Tables

### 5.1 Data

#### 5.1.1 Fishery-dependent data

Table 1: Landings for bottom trawl, midwater trawl, net, and hook-and-line (mt) fisheries from Washington, Oregon, and California.

## 5.2 Model results

Table 12: Specifications of the base assessment model for widow rockfish.

<i>Starting year</i>	1916
<i>Population characteristics</i>	
Maximum age	40
Genders	2
Population length bins	6-60 cm by 1 cm bins
Summary biomass (mt)	Age 4+
<i>Data characteristics</i>	
Data lengths	8-56 cm by 2 cm bins
Data ages	14611
First reference age for growth calcs	3
Second reference age for growth calcs	40
First mature age	3
Starting year of estimated recruitment	1900
<i>Fishery characteristics</i>	
Catchability	Analytical estimate
Fishery selectivity (not midwater trawl)	Asymptotic Double Normal

Midwater trawl fishery selectivity	Dome-shaped Double Normal
Juvenile survey selectivity	Double Normal
Triennial survey selectivity	Cubic spline with 3 nodes
WCGBTS selectivity	Cubic spline with 3 nodes
<i>Fishery time blocks</i>	
Bottom trawl selectiviy	1916 - 2001, 2002 -
Bottom trawl retention	1916 - 1981, 2011 -
Midwater trawl selectivitiy	1916–1982, 1983–2001, 2002–2010, 2011–
Midwater trawl retention	1916–1982, 1983–2001, 2002–2010, 2011–2016, 2017 -
Hake trawl selectivity	1916 - 2019, 2020 -
Hook-and-line selectivity	1916–2002, 2003–

Table 13: Parameter estimates, parameter bounds (low, high), estimation status, estimated standard deviation (SD), prior information [distribution(mean, SD)] used in the base model.

2036				5,405.10		4,833.43		32,400.2	0.398

Table 20: Summary table of 12-year projections beginning in 2027 for alternate states of nature based on the axis of uncertainty (a combination of M, h, and 2013 recruitment strength). Columns range over low, mid, and high state of nature, and rows range over different assumptions of total catch levels (discards + retained). Catches in 2025 and 2026 are allocated using the percentage of landings for each fleet from 2019-2024

			State of nature					
			Low		Base		High	
Management decision	Year	catch (mt)	Spawning biomass (mt)	Depletion (%)	Spawning biomass (mt)	Depletion (%)	Spawning biomass (mt)	Depletion (%)

## 6 Figures

### 6.1 Data

#### 6.1.1 Indices

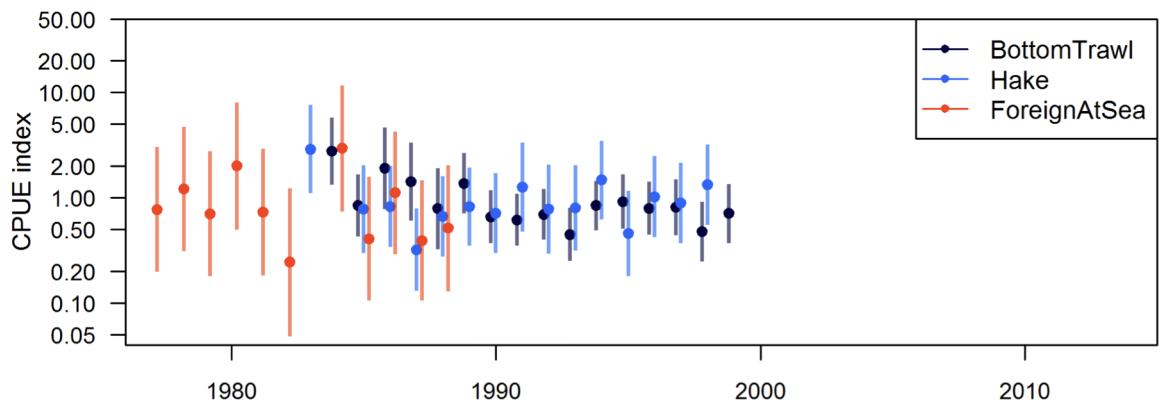

Figure 1: Fishery-dependent indices of abundance from the 2011 assessment scaled to the mean of their own series.

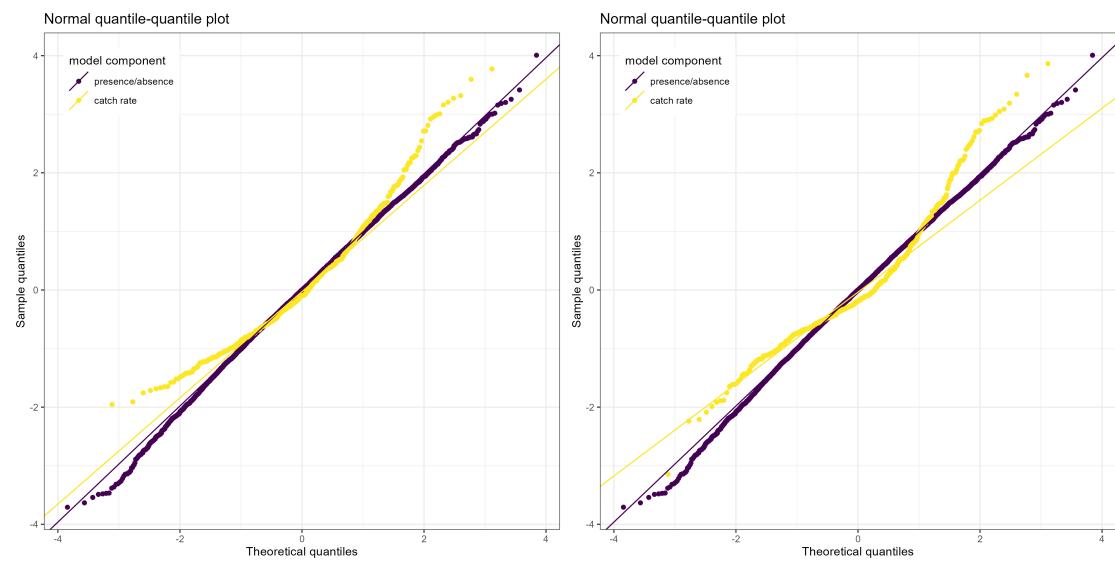

Figure 2: QQ plots for delta-gamma (panel 1) and delta-lognormal (panel 2, used in base model) sdmTMB index.

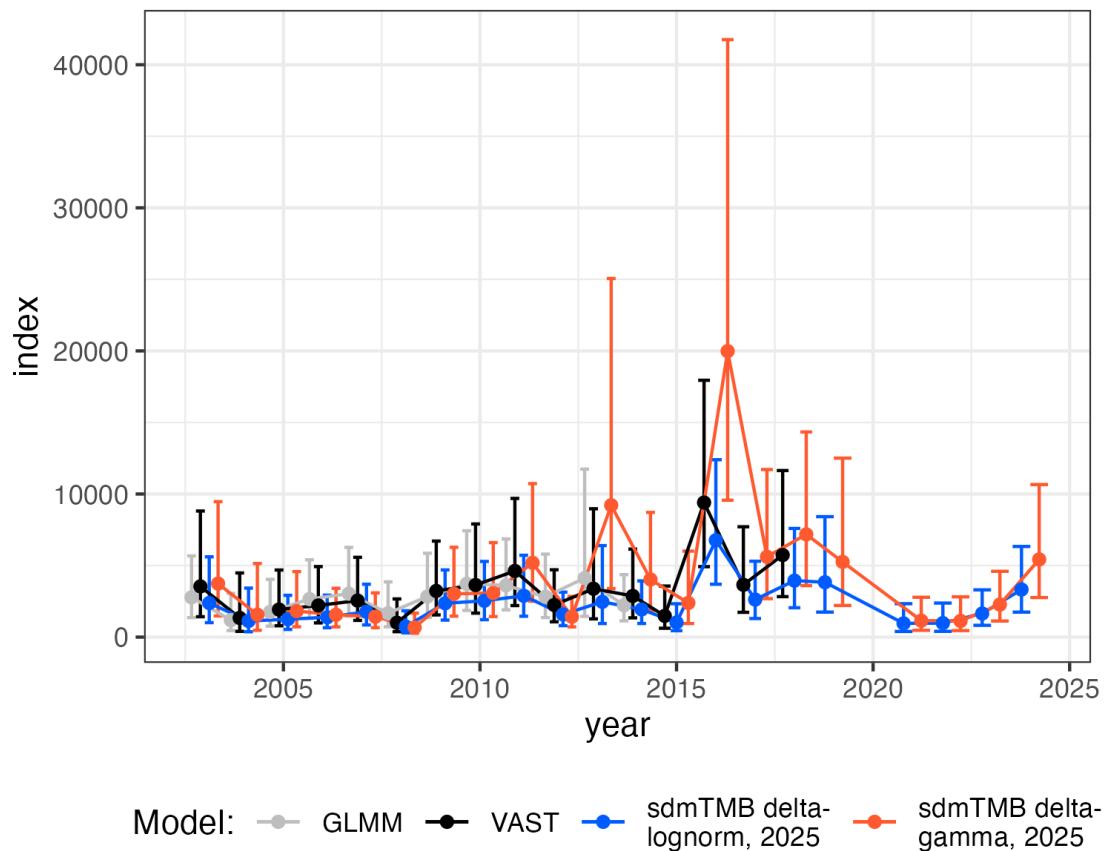

Figure 3: Comparison of the estimated index of relative abundance for the West Coast Groundfish Bottom Trawl Survey using a GLMM (gray line, 2015 stock assessment), VAST (black line, 2019 stock assessment), a delta-gamma sdmTMB index (blue line) and a delta-lognormal sdmTMB index (red line, used in base model). The error bars give 5 and 95% intervals for each survey.

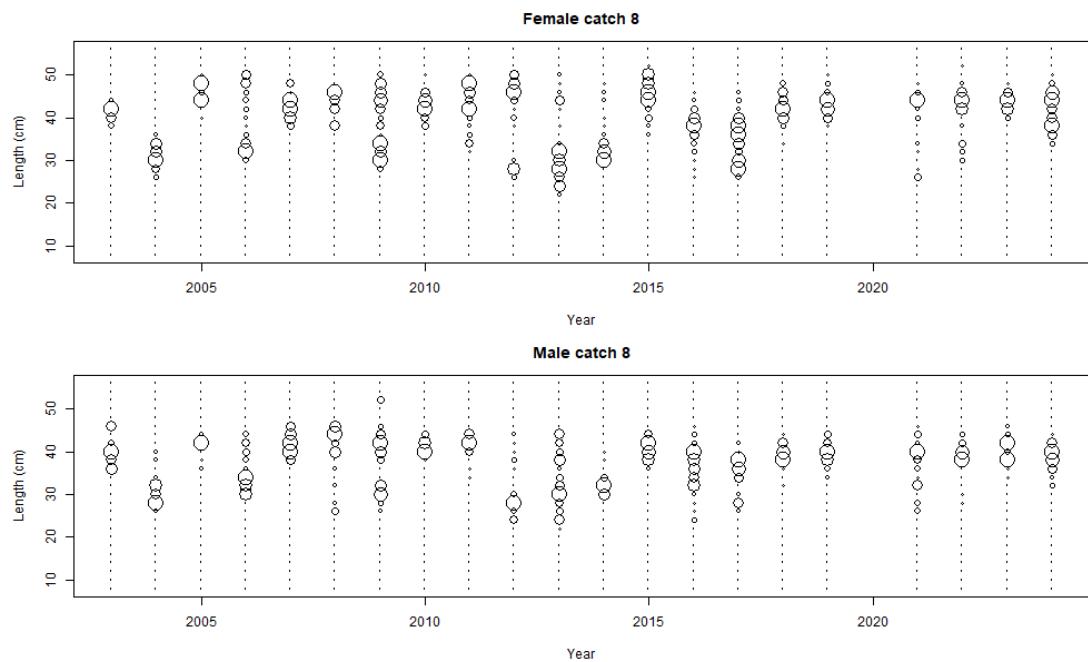

Figure 4: Expanded length compositions for the WCGBTS

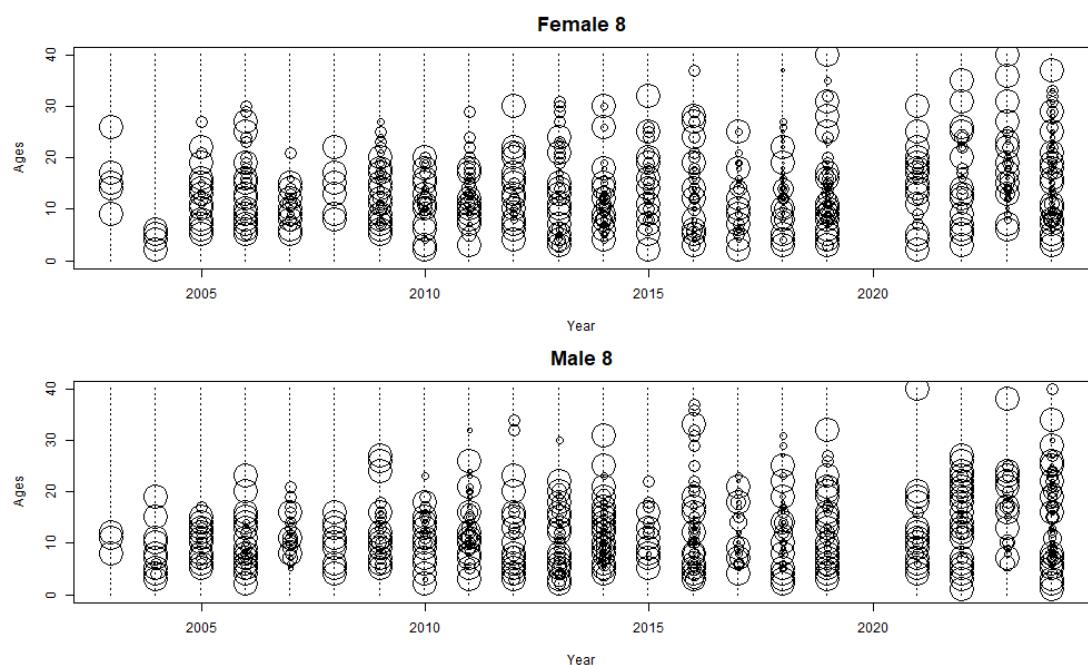

Figure 5: Expanded marginal age compositions from the WCGBTS.

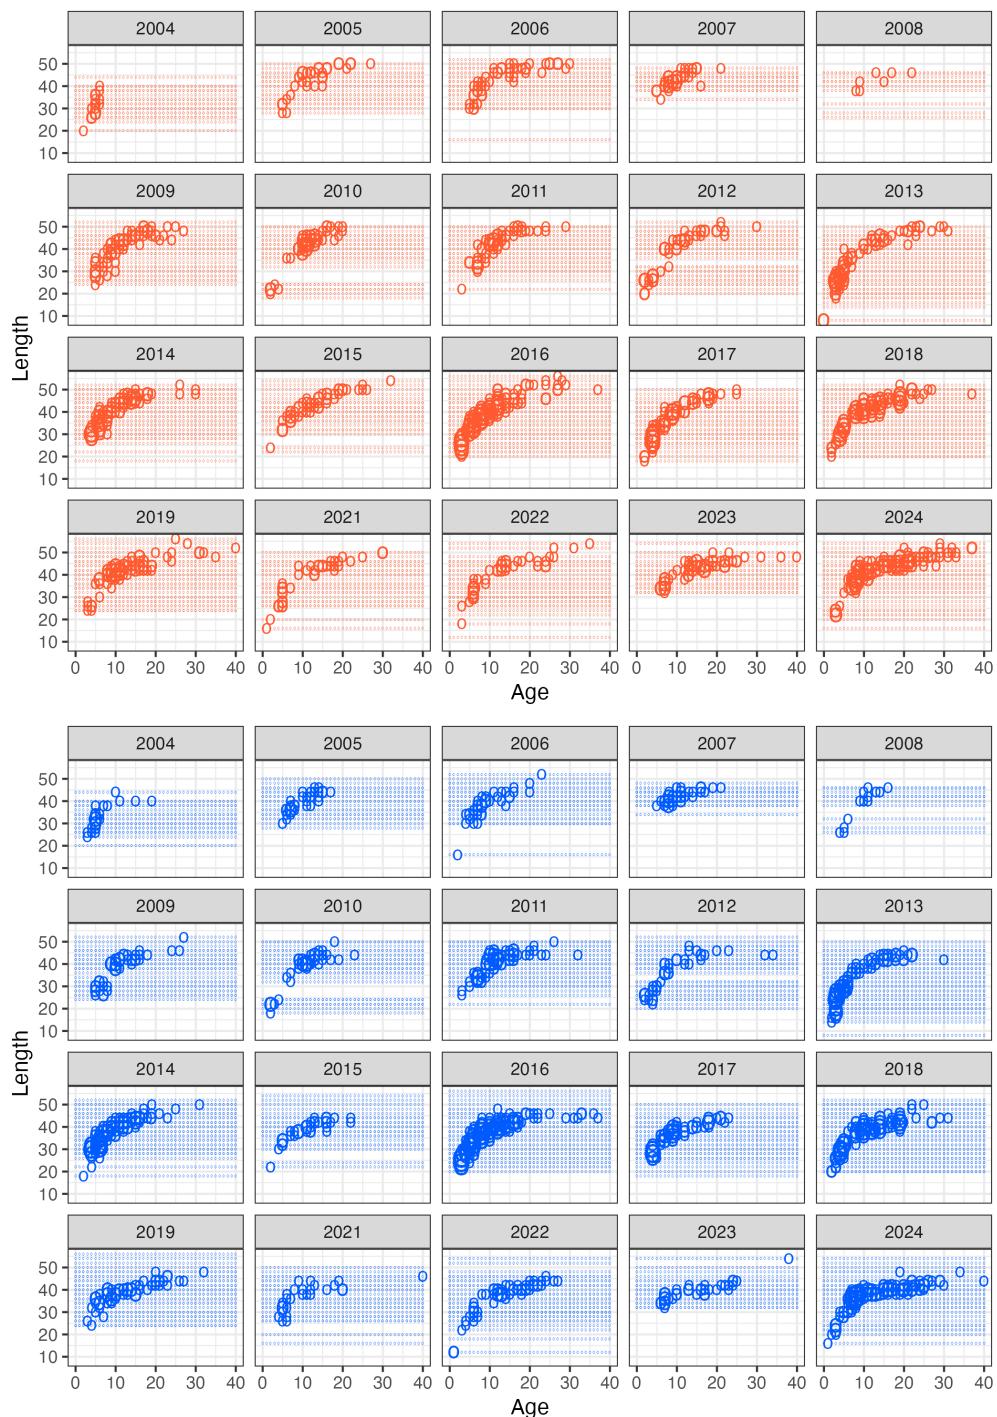

Figure 6: Conditional age-at-length from WCGBTS observations for females (red) and males (blue).

### 6.1.2 Composition data

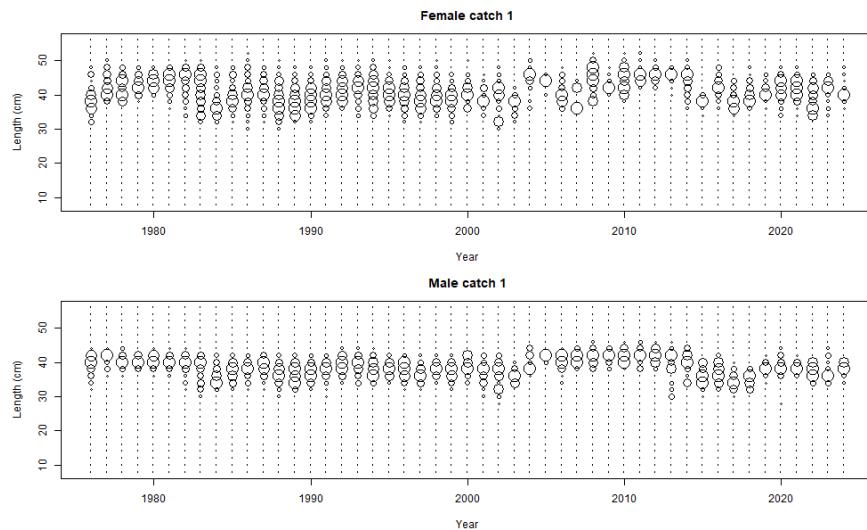

Figure 7: Expanded length compositions for the bottom trawl fishery. The area of the circle is proportional to the proportion-at-length.

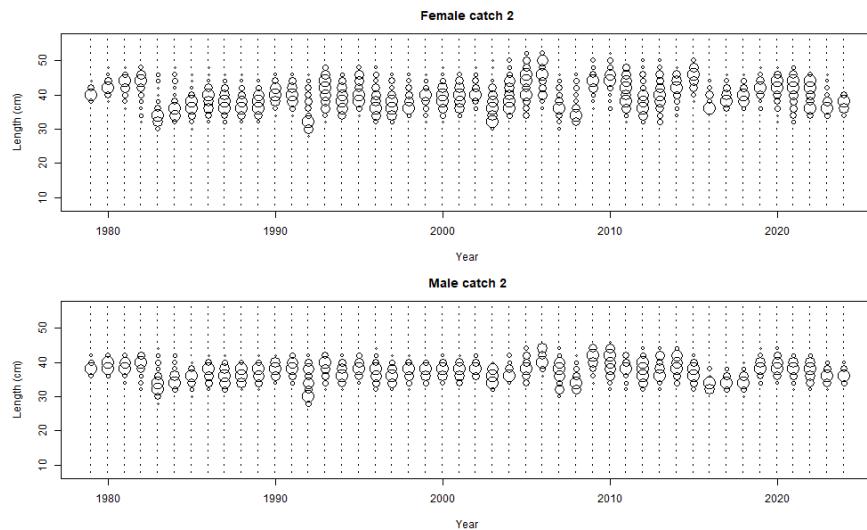

Figure 8: Expanded length compositions for the midwater trawl fishery. The area of the circle is proportional to the proportion-at-length.

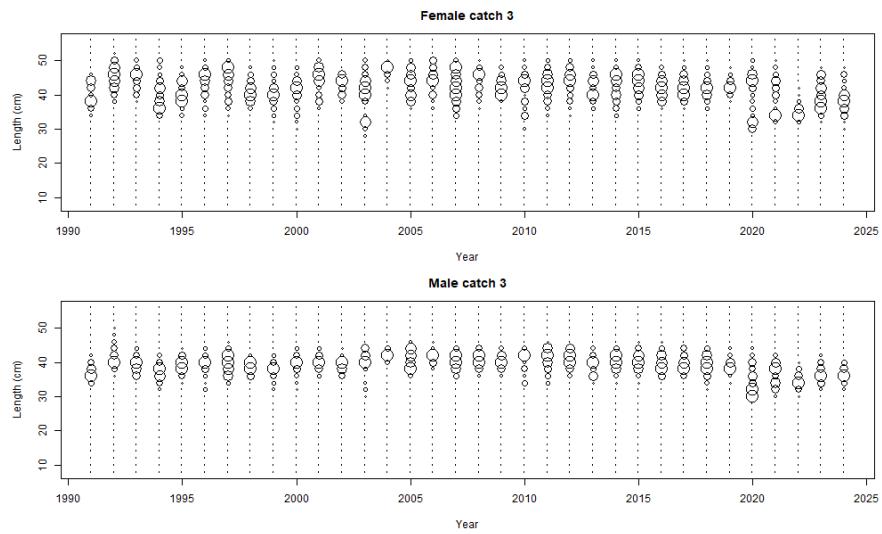

Figure 9: Expanded length compositions for the hake fishery. The area of the circle is proportional to the proportion-at-length.

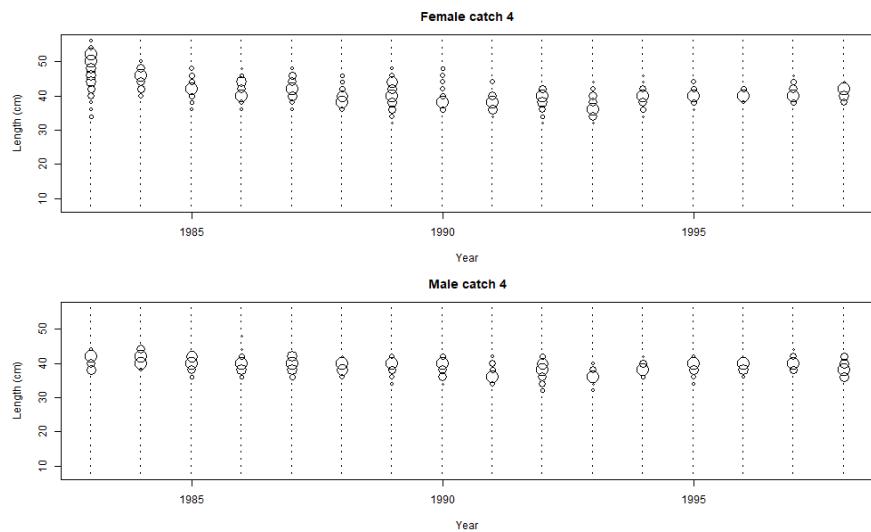

Figure 10: Expanded length compositions for the net fishery. The area of the circle is proportional to the proportion-at-length.

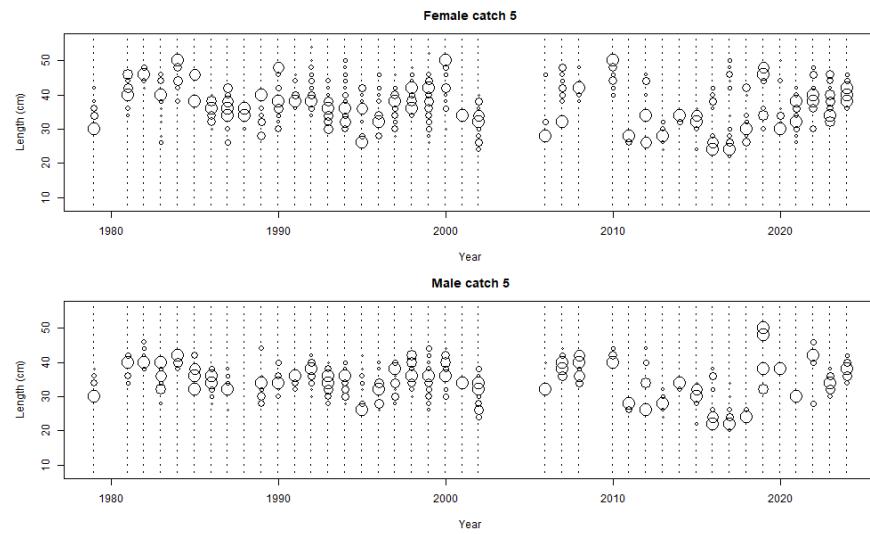

Figure 11: Expanded length compositions for the hook-and-line fishery. The area of the circle is proportional to the proportion-at-length.

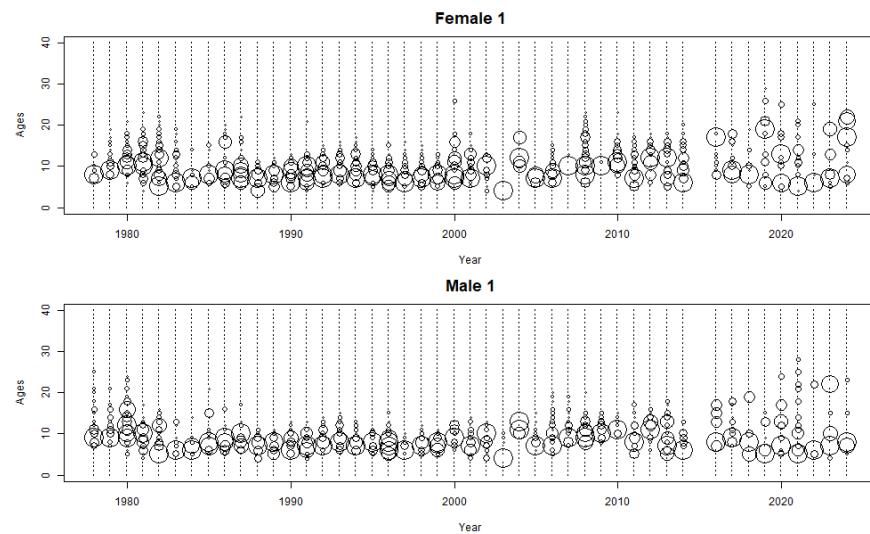

Figure 12: Expanded age compositions for the bottom trawl fishery. The area of the circle is proportional to the proportion-at-age.

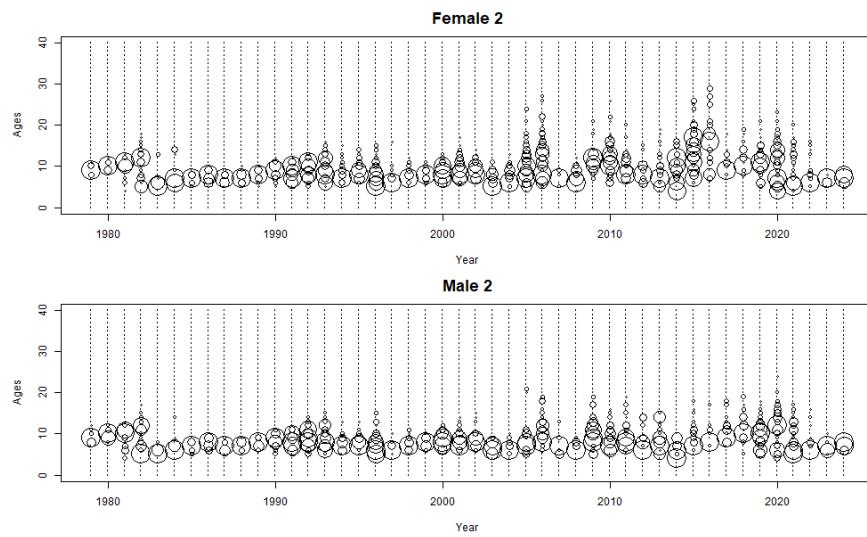

Figure 13: Expanded age compositions for the midwater trawl fishery. The area of the circles is proportional to the proportion-at-age.

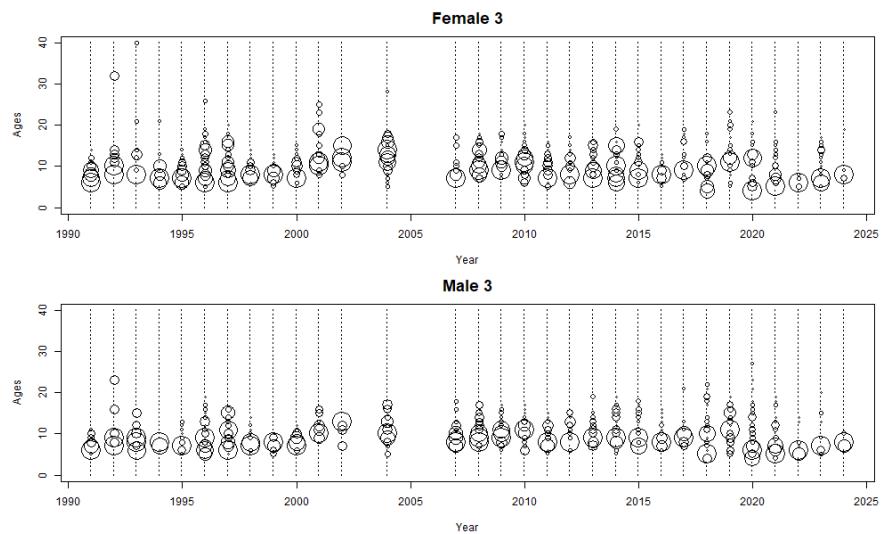

Figure 14: Expanded age compositions for the hake fishery. The area of the circles is proportional to the proportion-at-age.

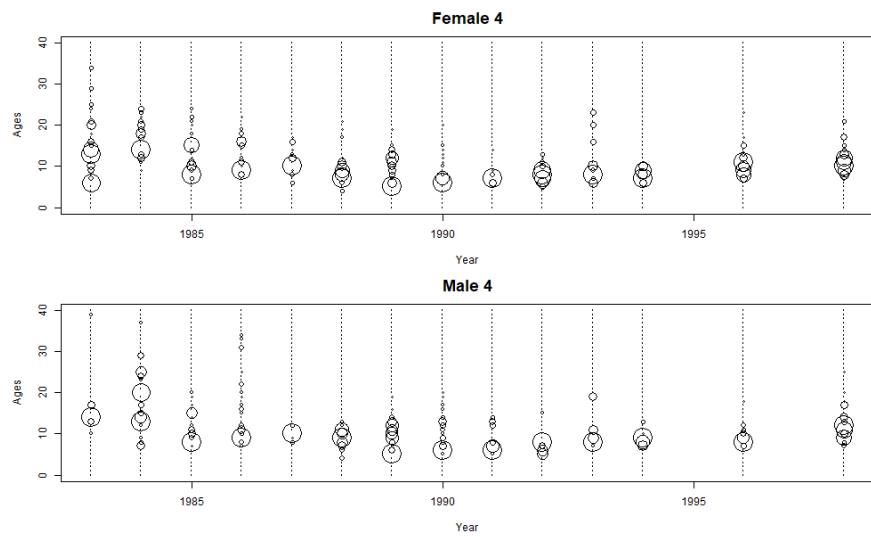

Figure 15: Expanded age compositions for the net fishery. The area of the circles is proportional to the proportion-at-age.

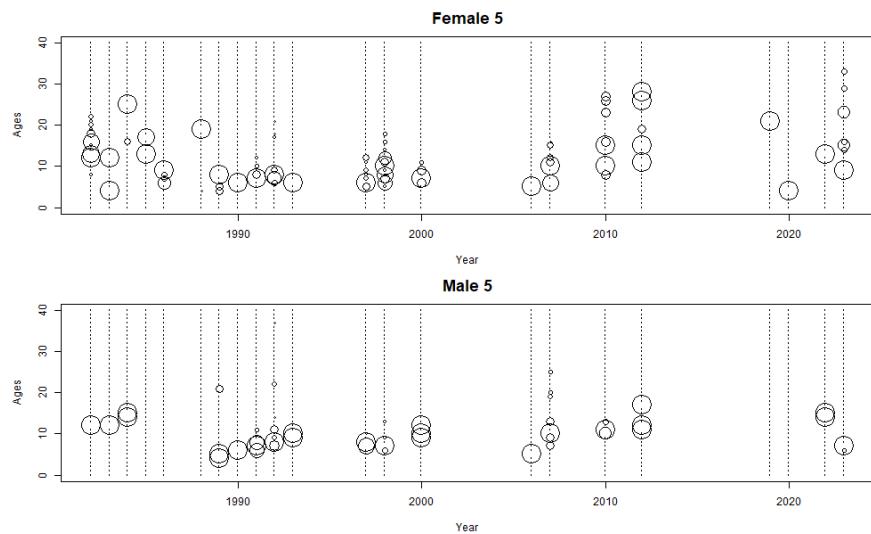

Figure 16: Expanded age compositions for the hook-and-line fishery. The area of the circles is proportional to the proportion-at-age.

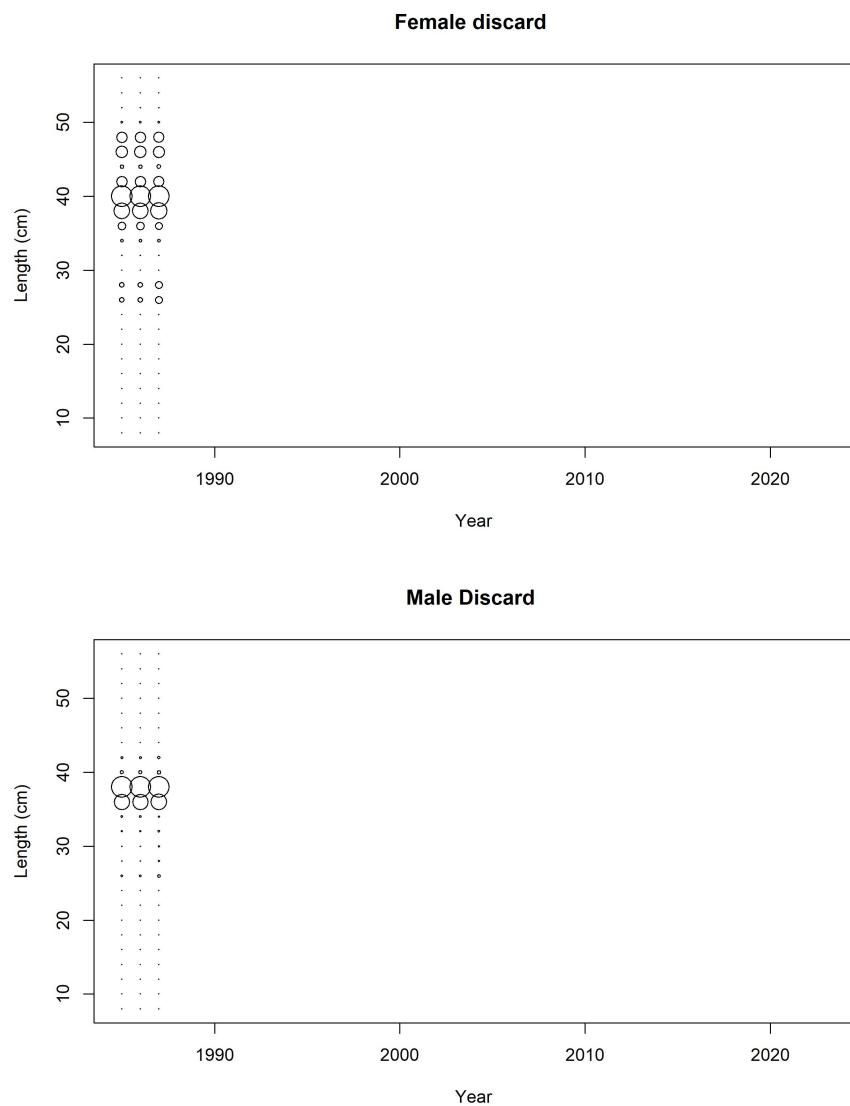

Figure 17: Length compositions for discards from the Pikitch study. The discard length comps were fitted into the model.

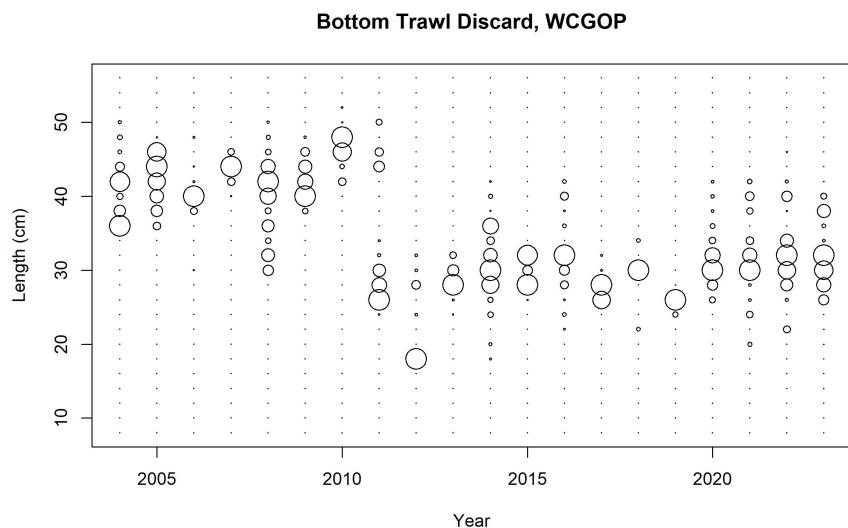

Figure 18: Length compositions of the discards for the bottom trawl.

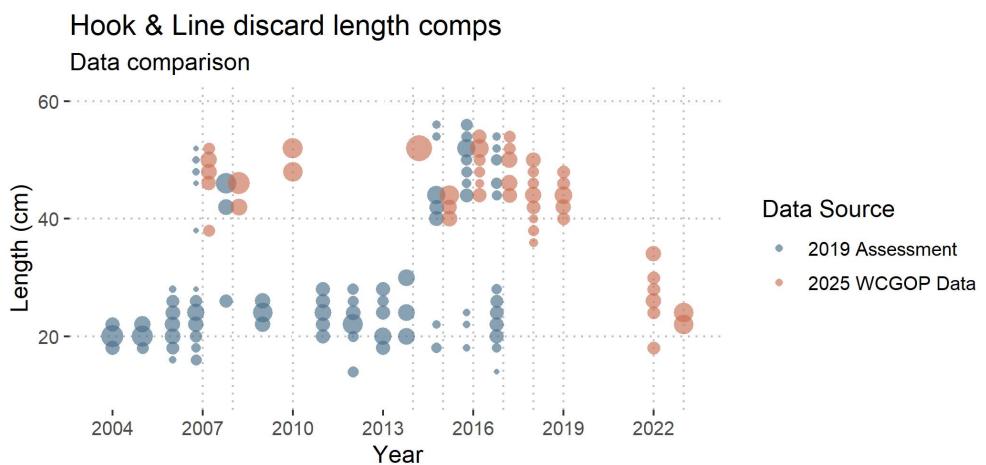

Figure 19: Comparison between discard data for the Hook & Line fleet from the 2019 assessment, which included nearshore fixed gear fleets, and discards queried from WCGOP for this assessment.

### 6.1.3 Biological data

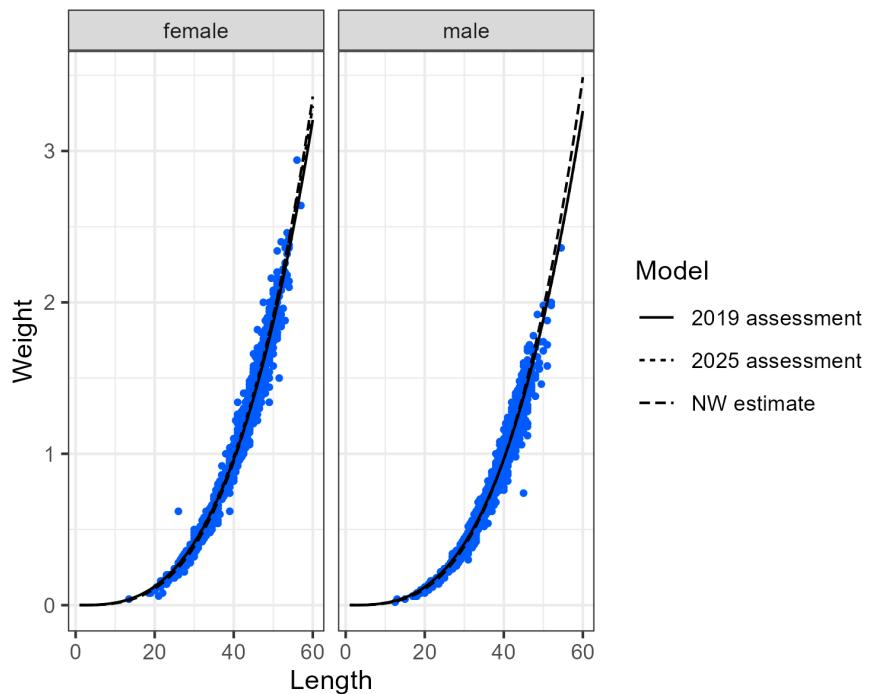

Figure 20: Fits to weight-at-length observations (dashed line) for females (left) and males (right) using observations from all data sources. The weight-at-length curve from the 2019 assessment is indicated with a solid line.

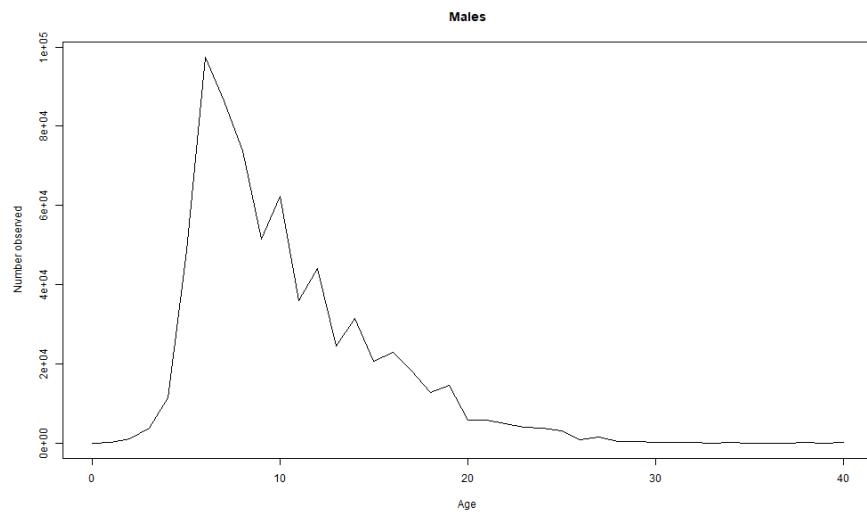

Figure 21: Number at age observed from all data for female and male widow rockfish.

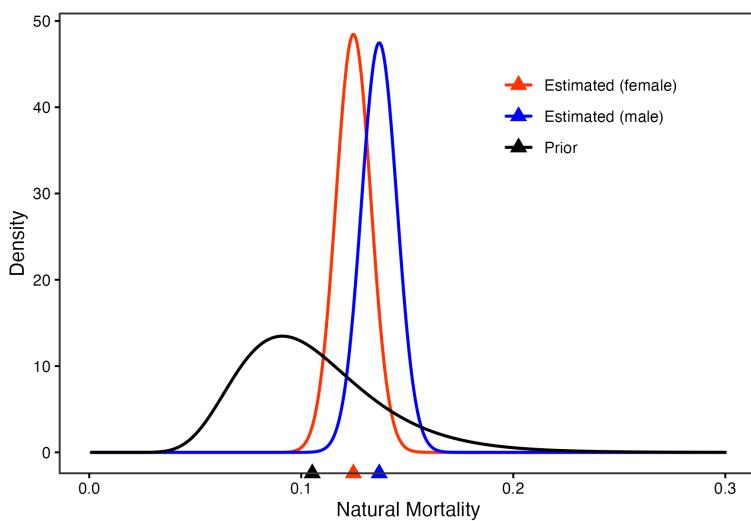

Figure 22: The prior for natural mortality (black,  $M$ , yr $^{-1}$ ) and the estimated  $M$  for females (red) and males (blue) with asymptotic approximation to the sampling distribution. The means of each distribution are shown with triangles.

## 6.2 Model

### 6.2.1 Bridging

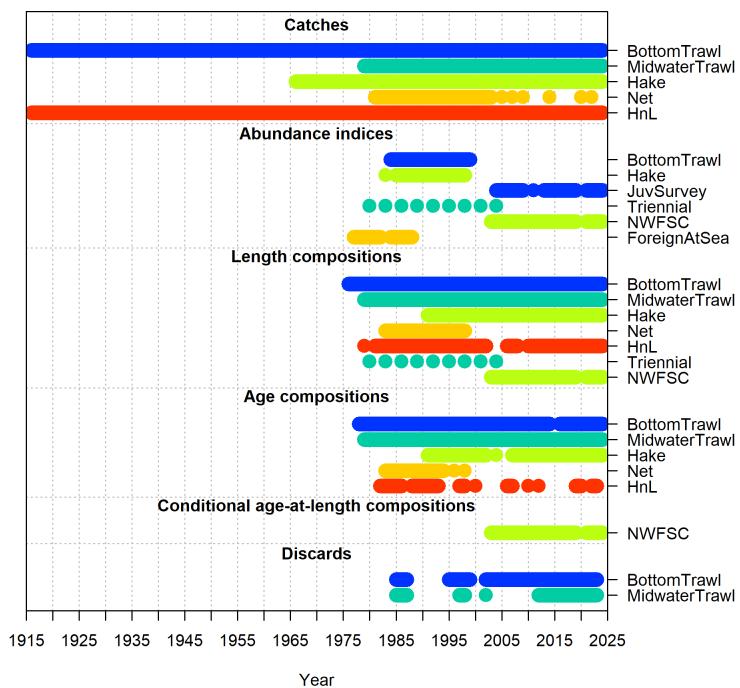

Figure 23: Data sources by type and year that were used in the base model.

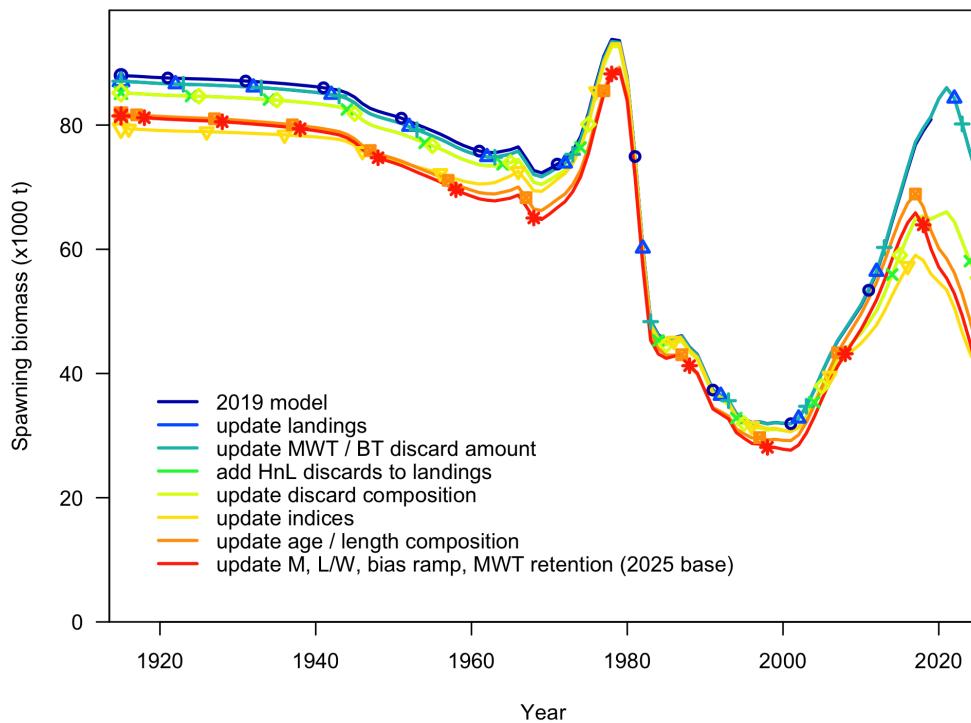

Figure 24: Time series of spawning stock biomass (SSB) estimates from model runs bridging from the 2019 assessment (dark blue) to the current base model (red). For illustration purposes, the addition of midwater and bottom trawl discards (without updating hook-and-line discards) precedes the addition of hook-and-line discards to hook-and-line landings. Some bridging steps with minimal impact on SSB are grouped (including updating mortality priors, length/weight regression estimates, stock-recruitment bias ramp estimation, and the addition of a block on midwater retention).

### 6.2.2 Selectivity

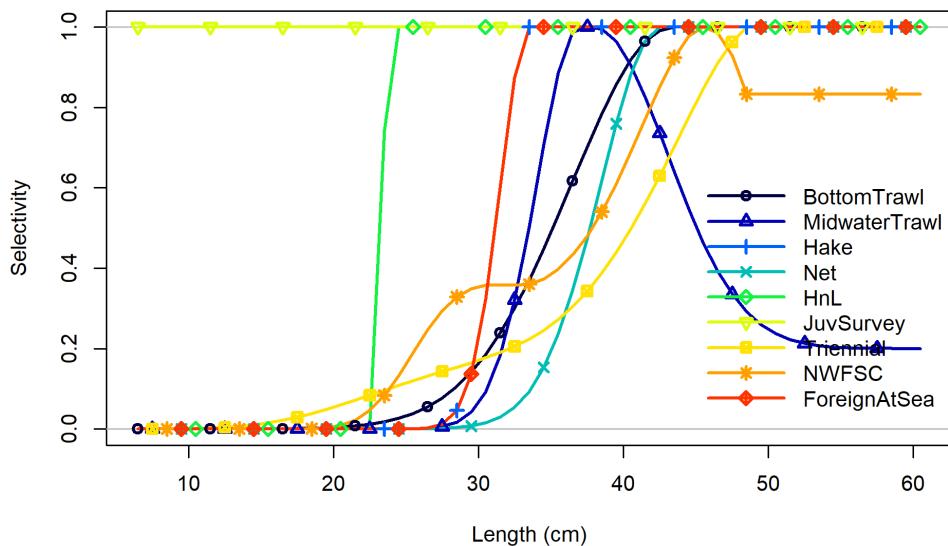

Figure 25: Estimated selectivity for different fleets and surveys.

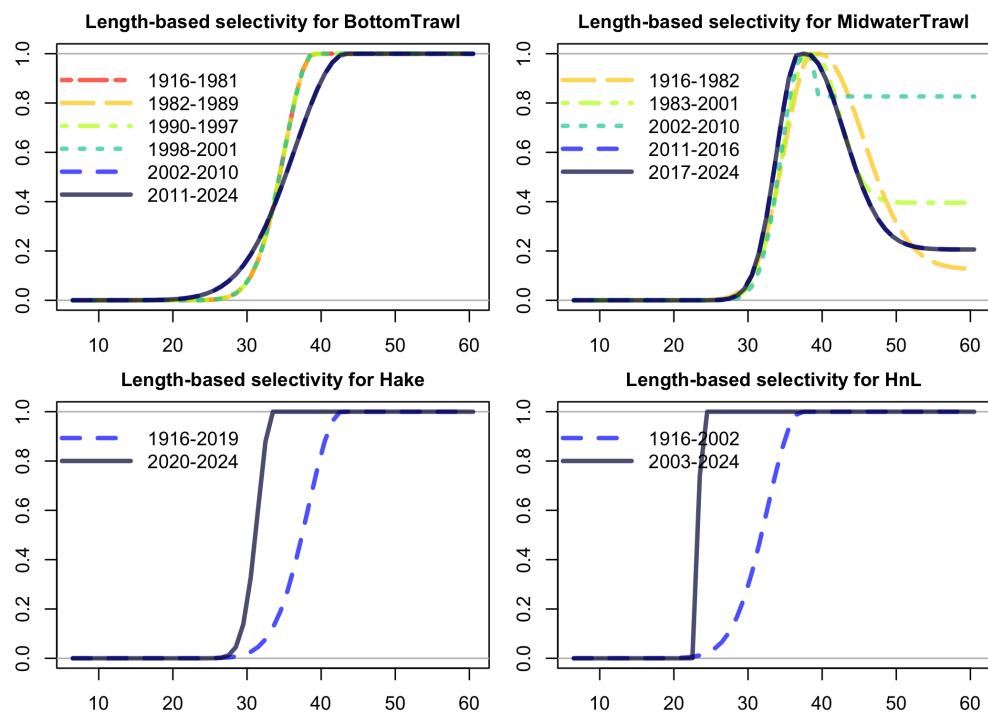

Figure 26: Estimated selectivity curves by time block for bottom trawl, midwater trawl, hake, and hook-and-line fleets.

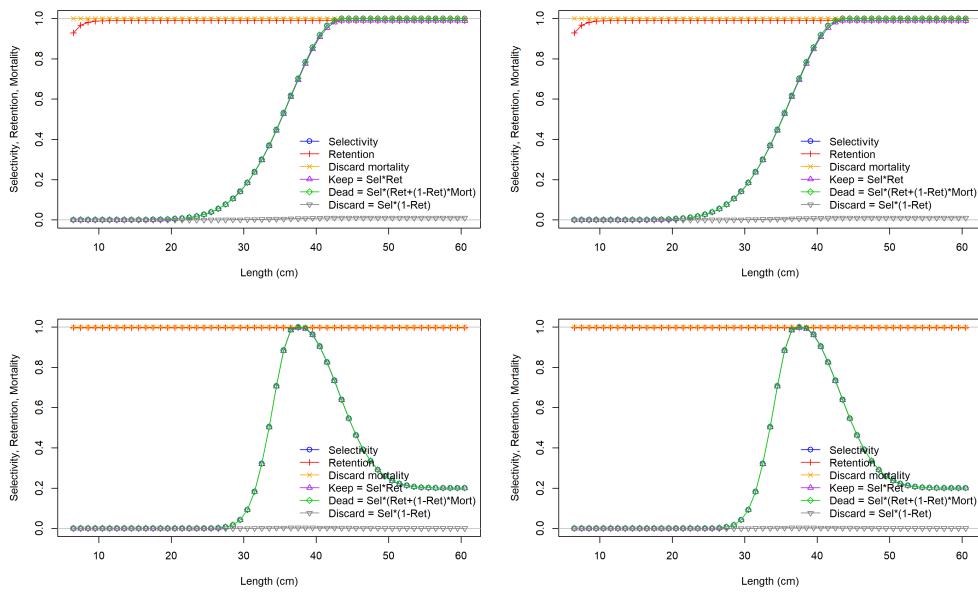

Figure 27: Estimated selectivity for Bottom Trawl (top row) and Midwater Trawl (bottom row) for males (left column) and females (right column)

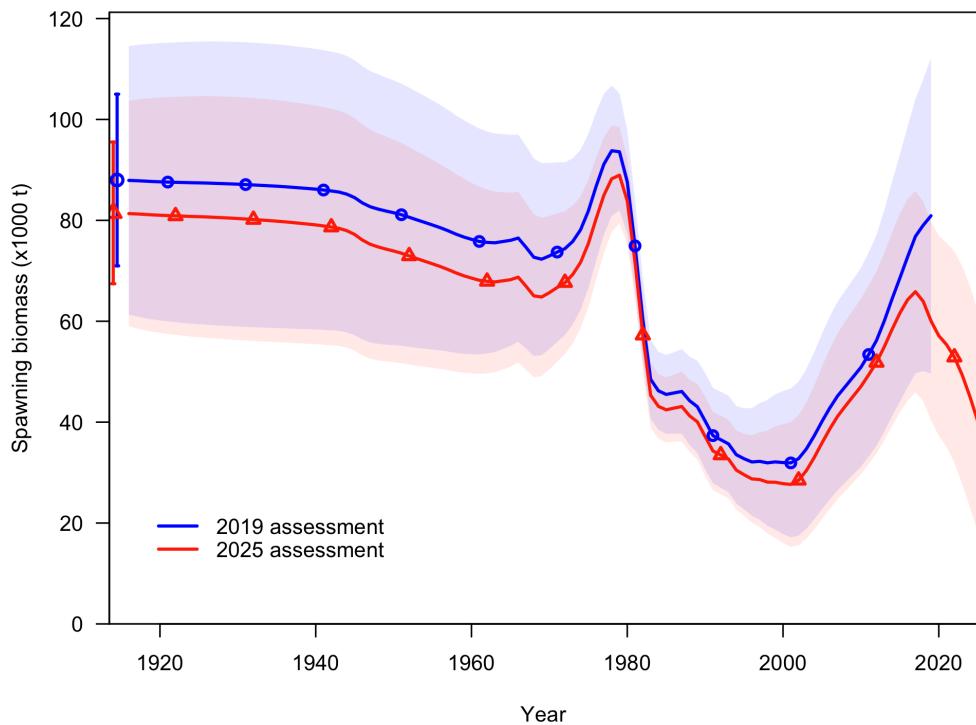

Figure 28: Time series of spawning stock biomass (SSB) estimates and asymptotic 95% confidence intervals estimates from 2019 and 2025 base models.

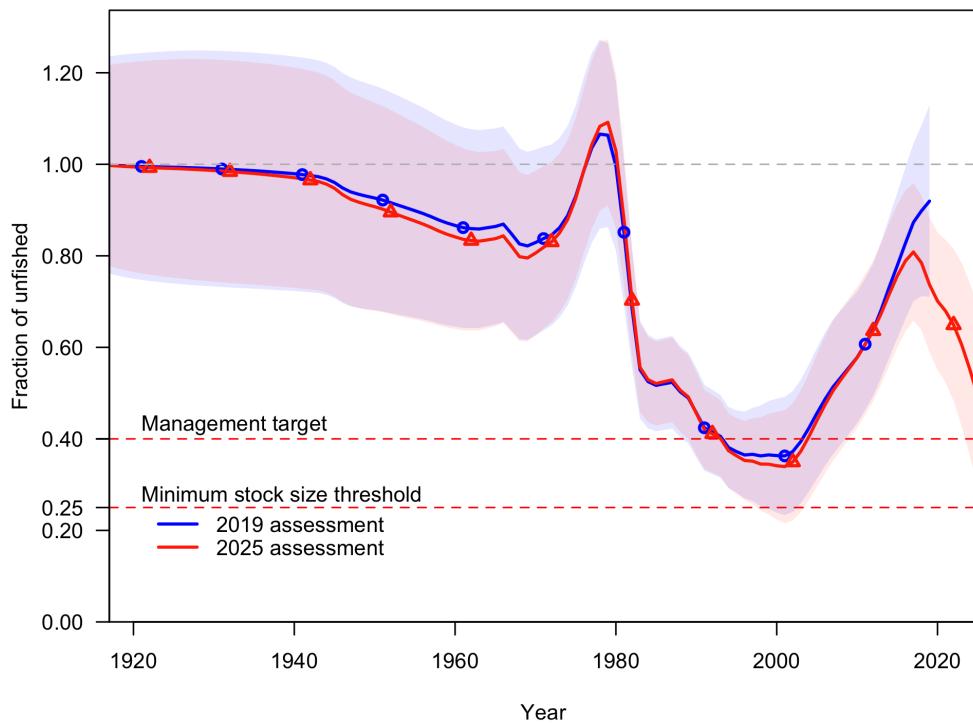

Figure 29: Time series of fraction of unfished spawning stock biomass estimates and asymptotic 95% confidence intervals estimates from 2019 and 2025 base models.

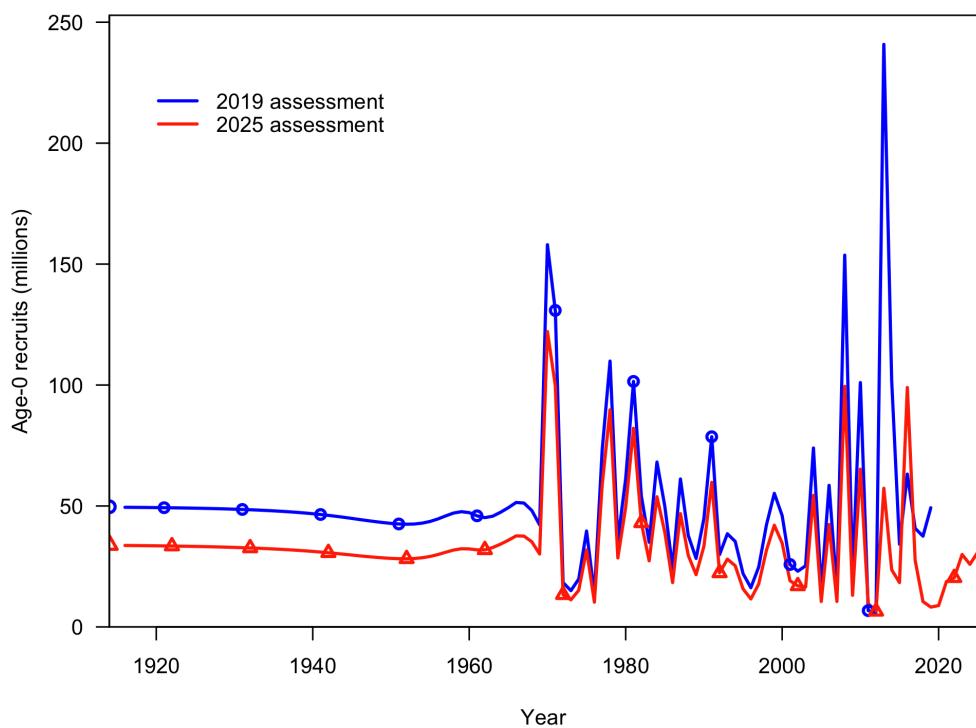

Figure 30: Estimates of age-0 recruits (in millions of individuals) from 2019 and 2025 base models.

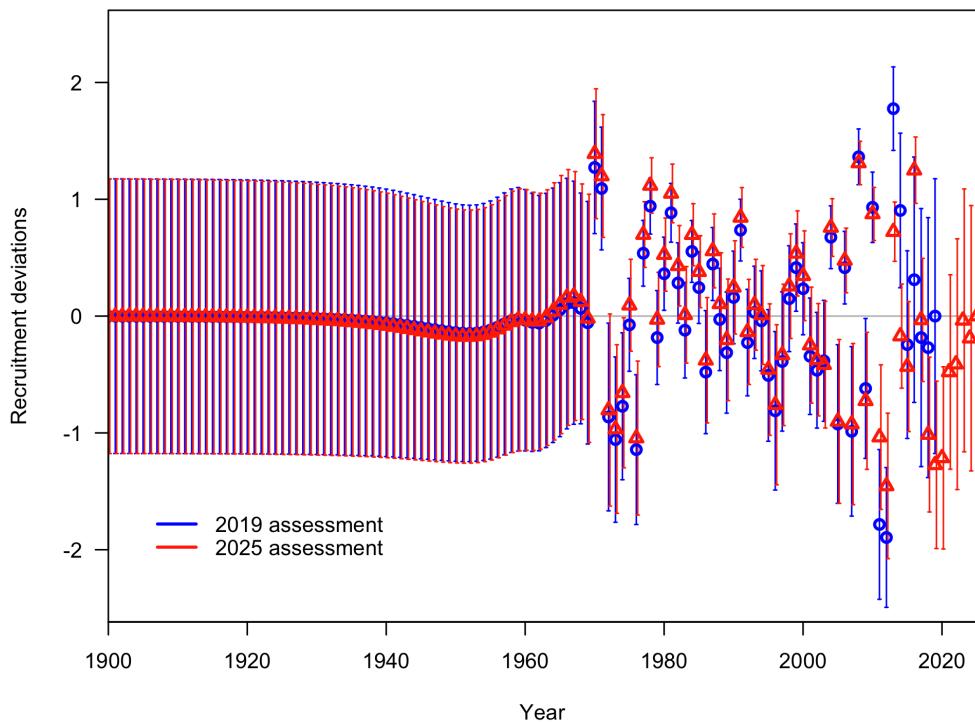

Figure 31: Estimates of age-0 (log-)recruitment deviations from 2019 and 2025 base models, with asymptotic 95% confidence intervals.

### 6.2.3 Biology

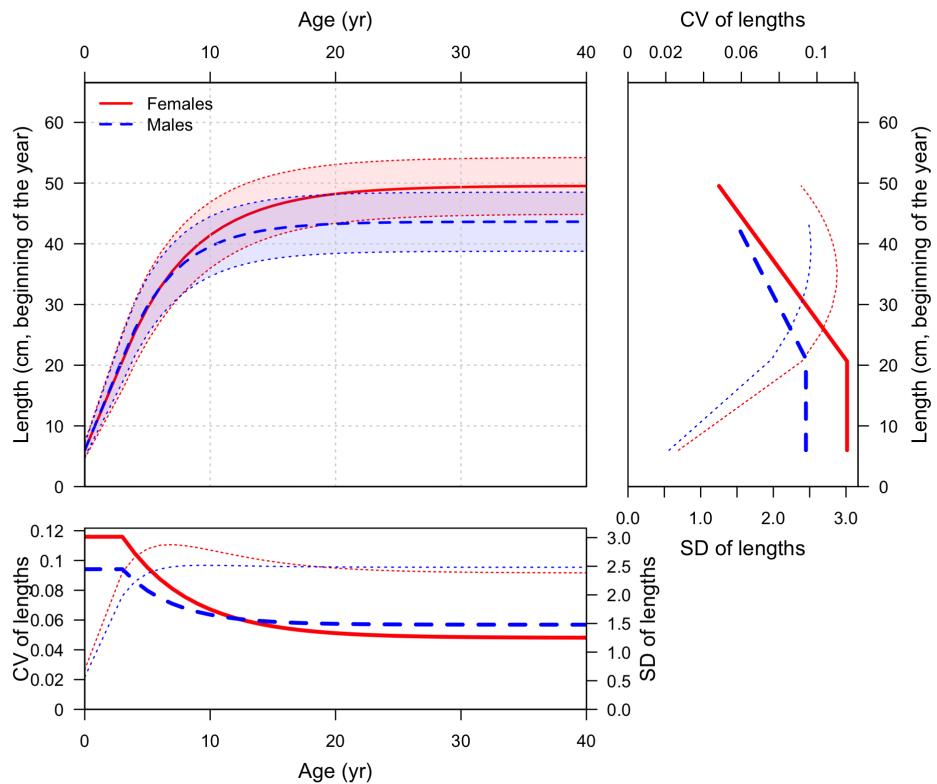

Figure 32: Length at age (top-left panel) with estimated coefficient of variation (CV, thick line) and calculated standard deviation (SD, thin line) versus length at age in the top-right panel and versus age in the lower-left panel.

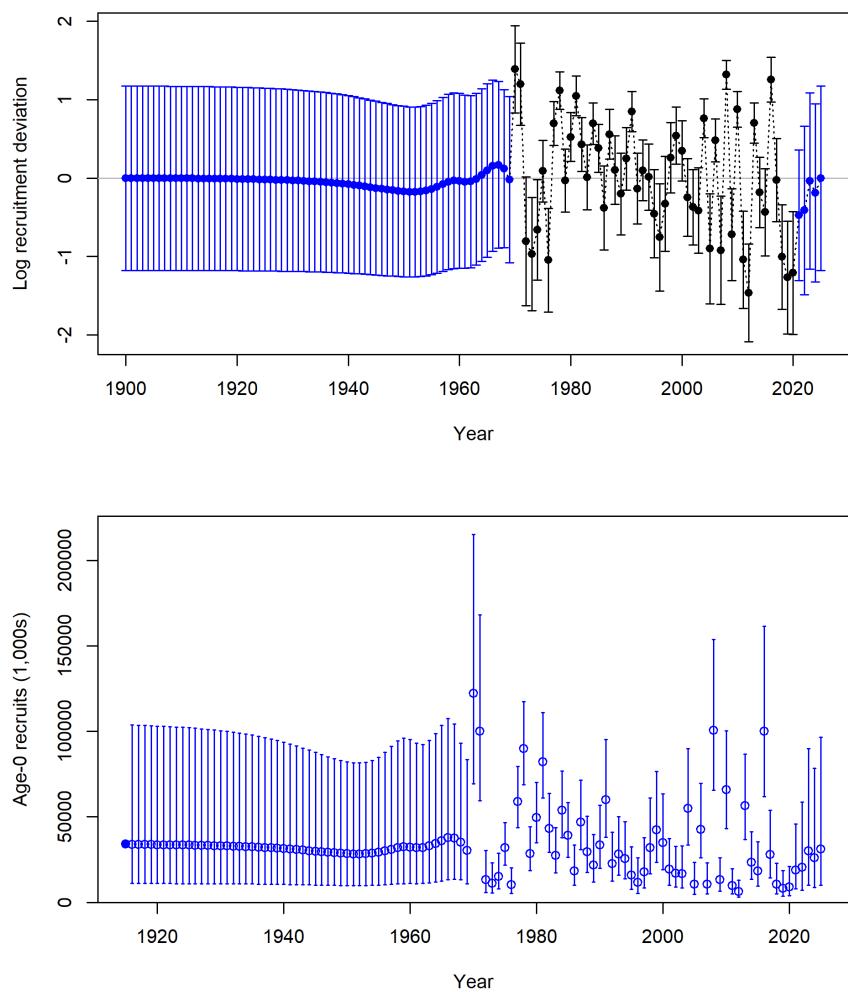

Figure 33: Estimates of recruitment (upper) and recruitment deviates (lower) with approximate asymptotic 95% confidence intervals (vertical lines) from the MLE estimates.

#### 6.2.4 Fits to data

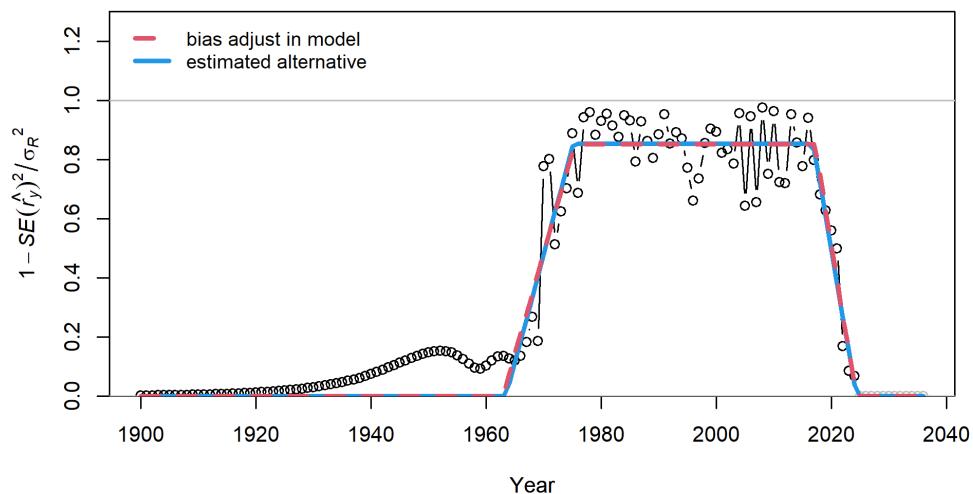

Figure 34: Estimated and input recruitment bias adjustment ramp. Red line shows current settings for bias adjustment ramp. Red line shows current settings for bias adjustment specified in the model. Blue line shows least squares estimate of alternative bias adjustment relationship for recruitment deviations.

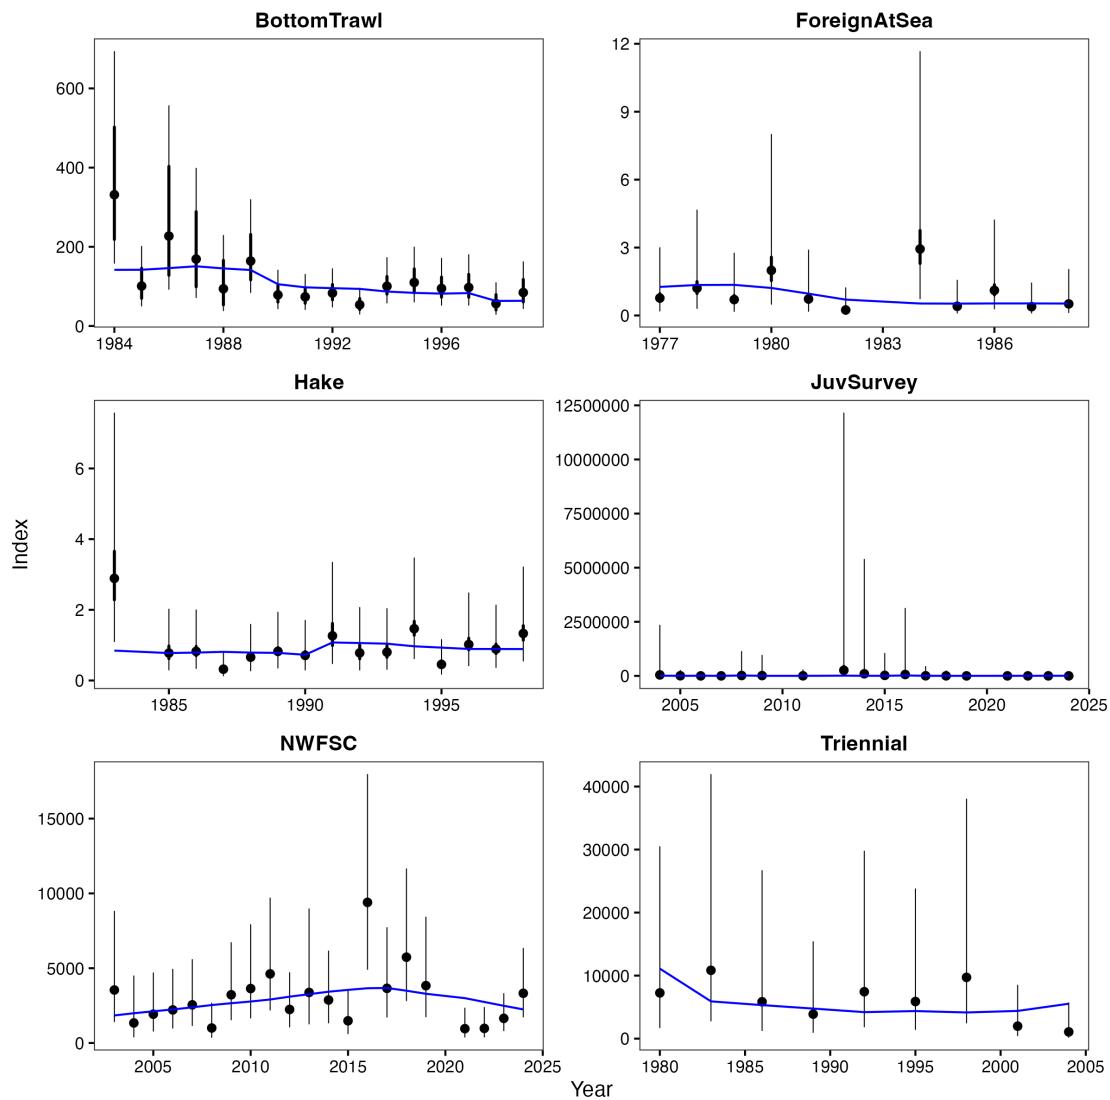

Figure 35: Fits (blue lines) to the abundance estimates (black points) for the base model. A separate  $q$  is estimated for the Hake series starting in 1991. Except the juvenile survey (counts) all indices are biomass-based. 95% confidence intervals are shown in the input standard errors. Thicker lines (if present) indicate input uncertainty before addition of the estimated additional uncertainty parameter.

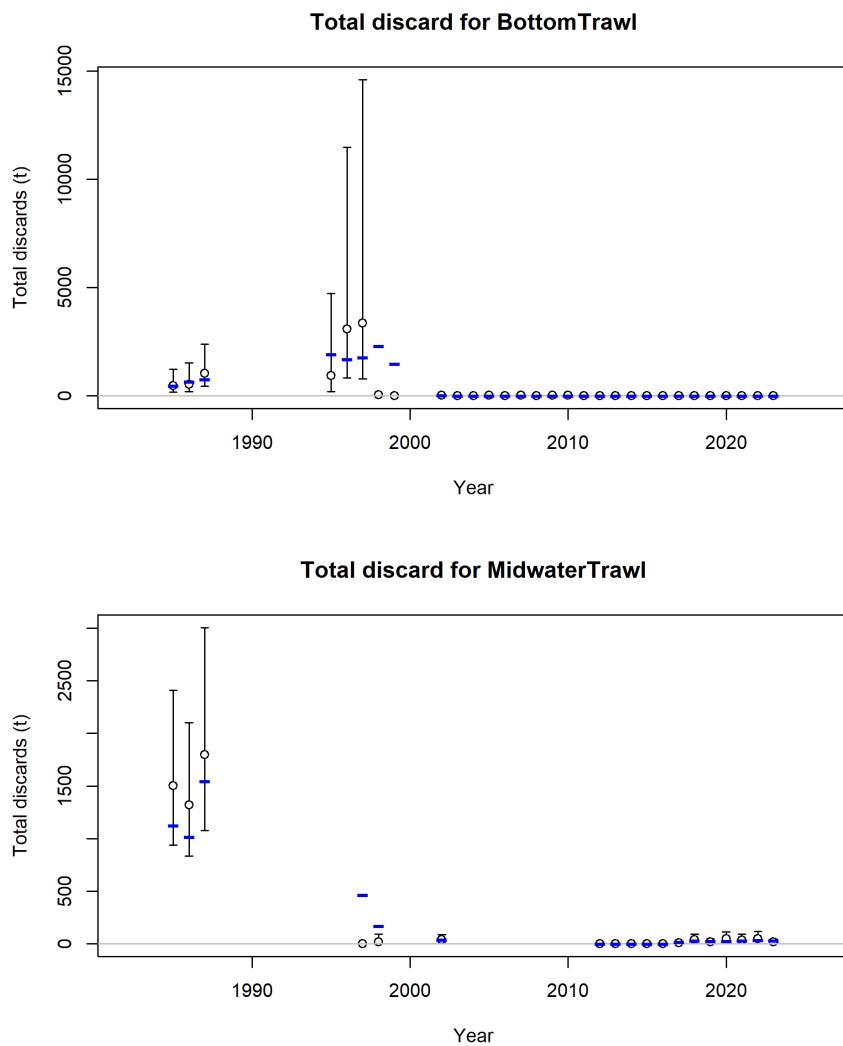

Figure 36: Predicted (blue line) and observed (open circles) discards for the bottom trawl (top) and midwater trawl (bottom) fleets from the base model. 95% confidence intervals are shown for the observations.

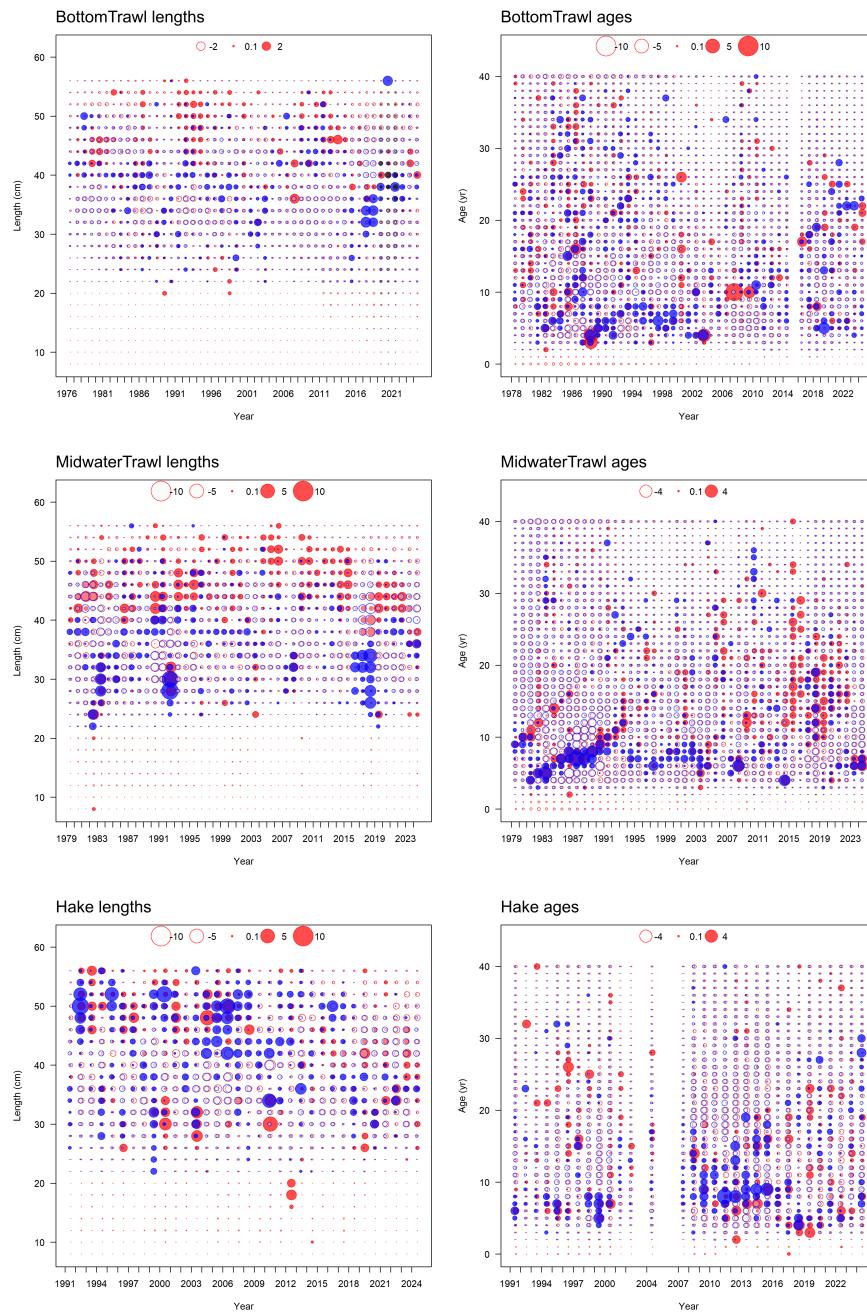

Figure 37: Pearson residuals for fits to length frequency data (left) and age frequency data (right) for landings from the trawl commercial fleets (rows). Filled circles indicate that the fitted proportion was less than the observed proportion. Red indicates females, blue males, and gray unsexed.

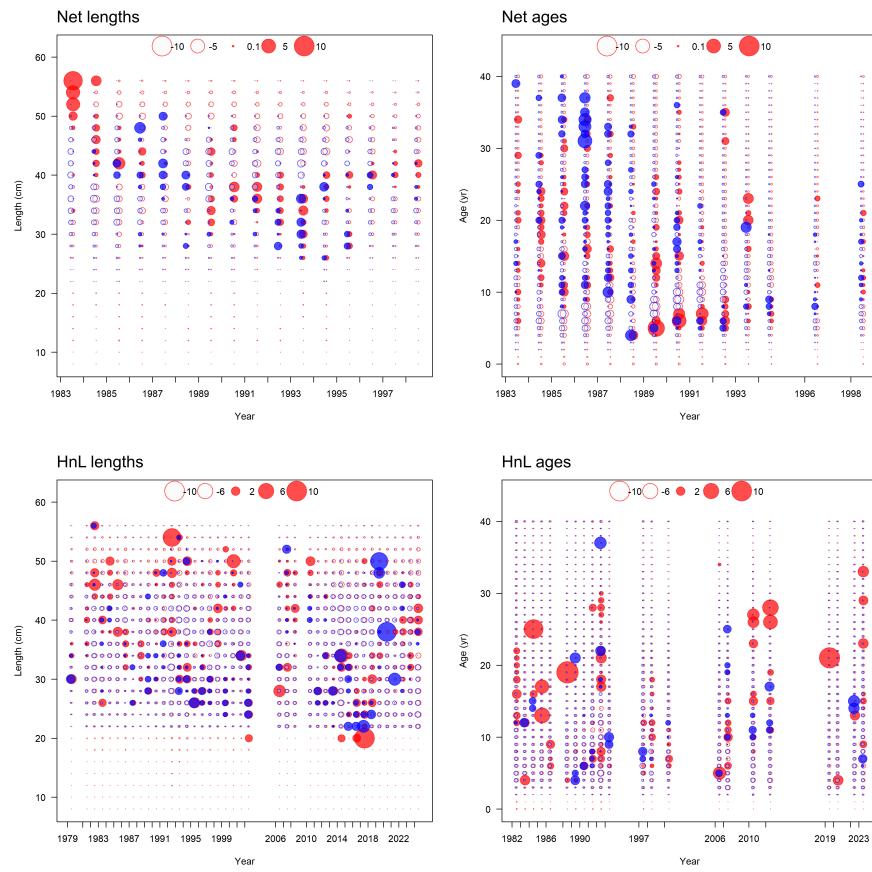

Figure 38: Pearson residuals for fits to length frequency data (left) and age frequency data (right) for landings from the net and hook-and-line commercial fleets (rows). Filled circles indicate that the fitted proportion was less than the observed proportion. Red indicates females, blue males, and gray unsexed.

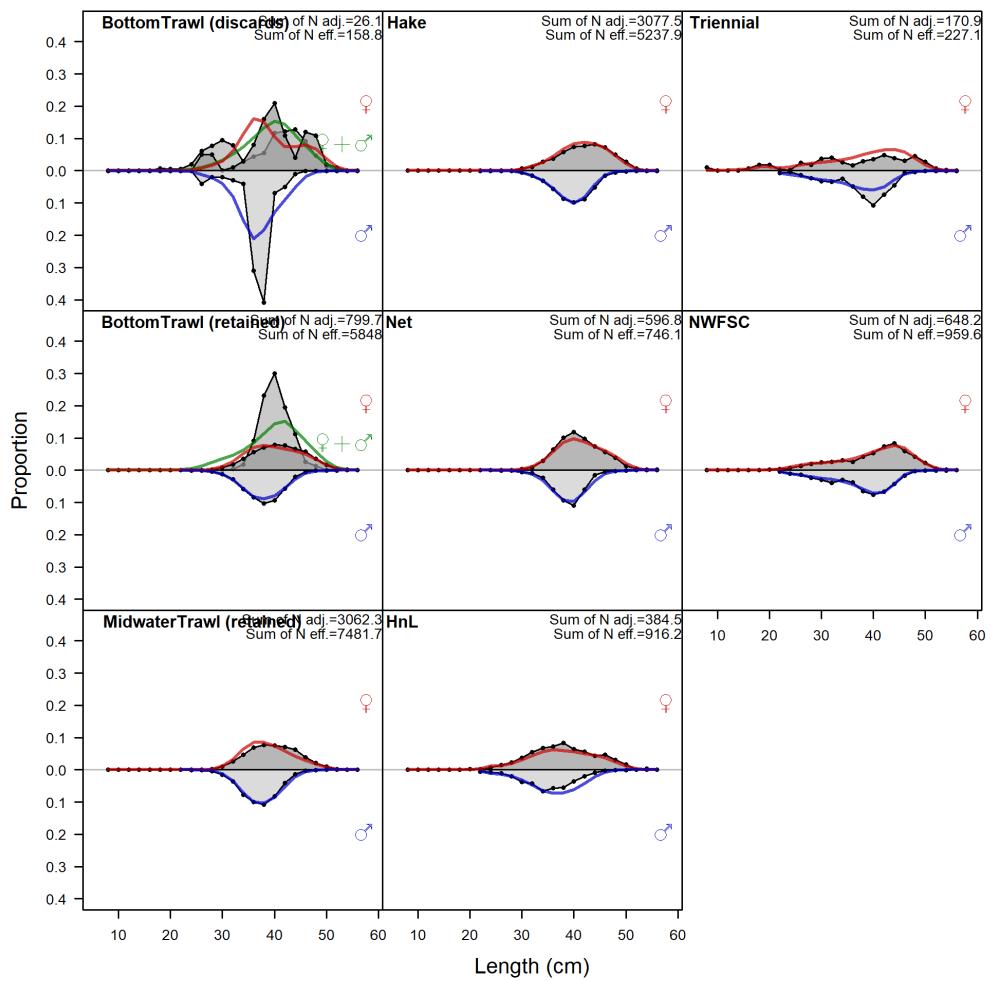

Figure 39: Combined length frequencies for all years from fishery (retained catch) and survey length frequency data (points). Fits are shown by the red line (females) and blue line (males).

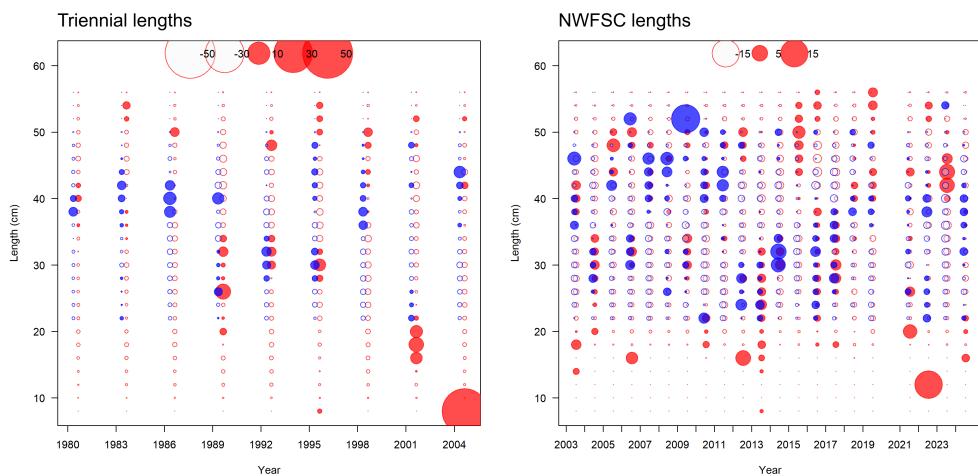

Figure 40: Pearson residuals for fits to the triennial survey length frequency data (left) and WCGBTS length frequency data (right). Filled circles indicate that the fitted proportion was less than the observed proportion. Red indicates females, blue males, and gray unsexed.

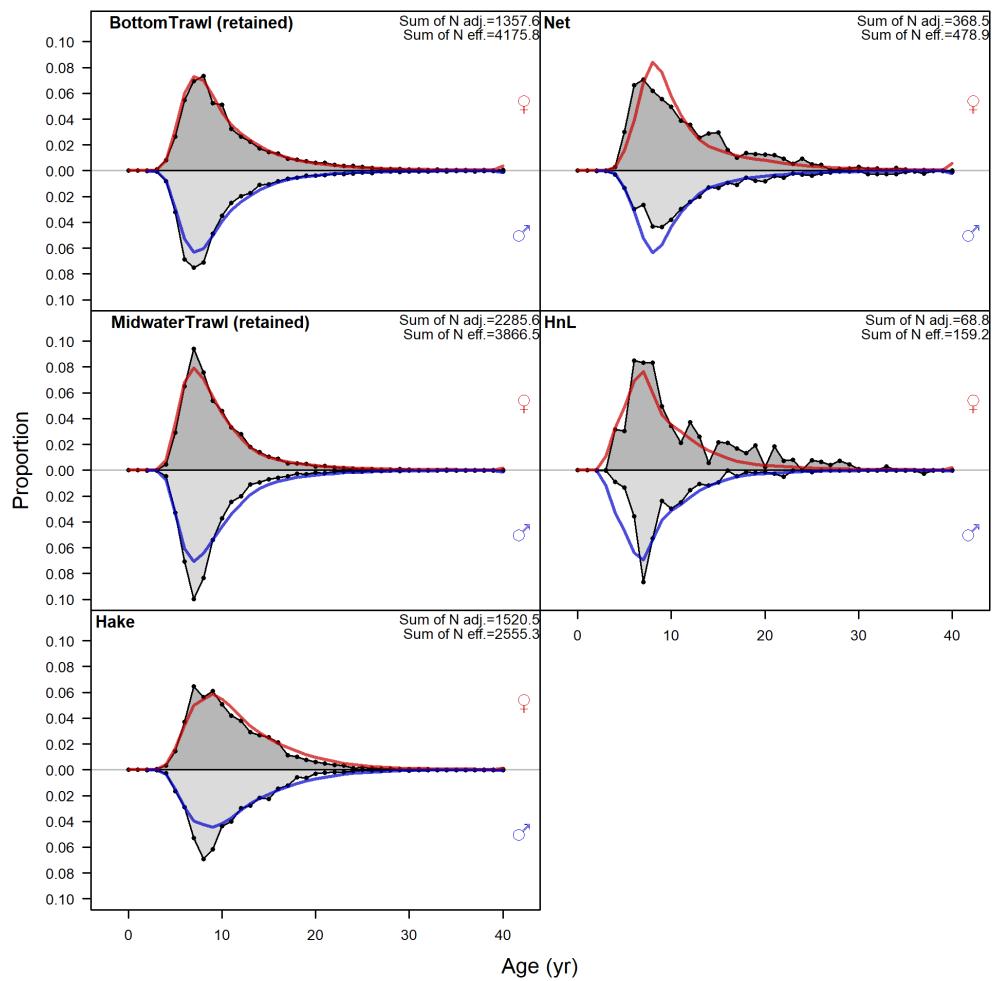

Figure 41: Combined age frequencies for all years from fishery (retained catch) and survey length frequency data (points). Fits are shown by the red line (females) and blue line (males).

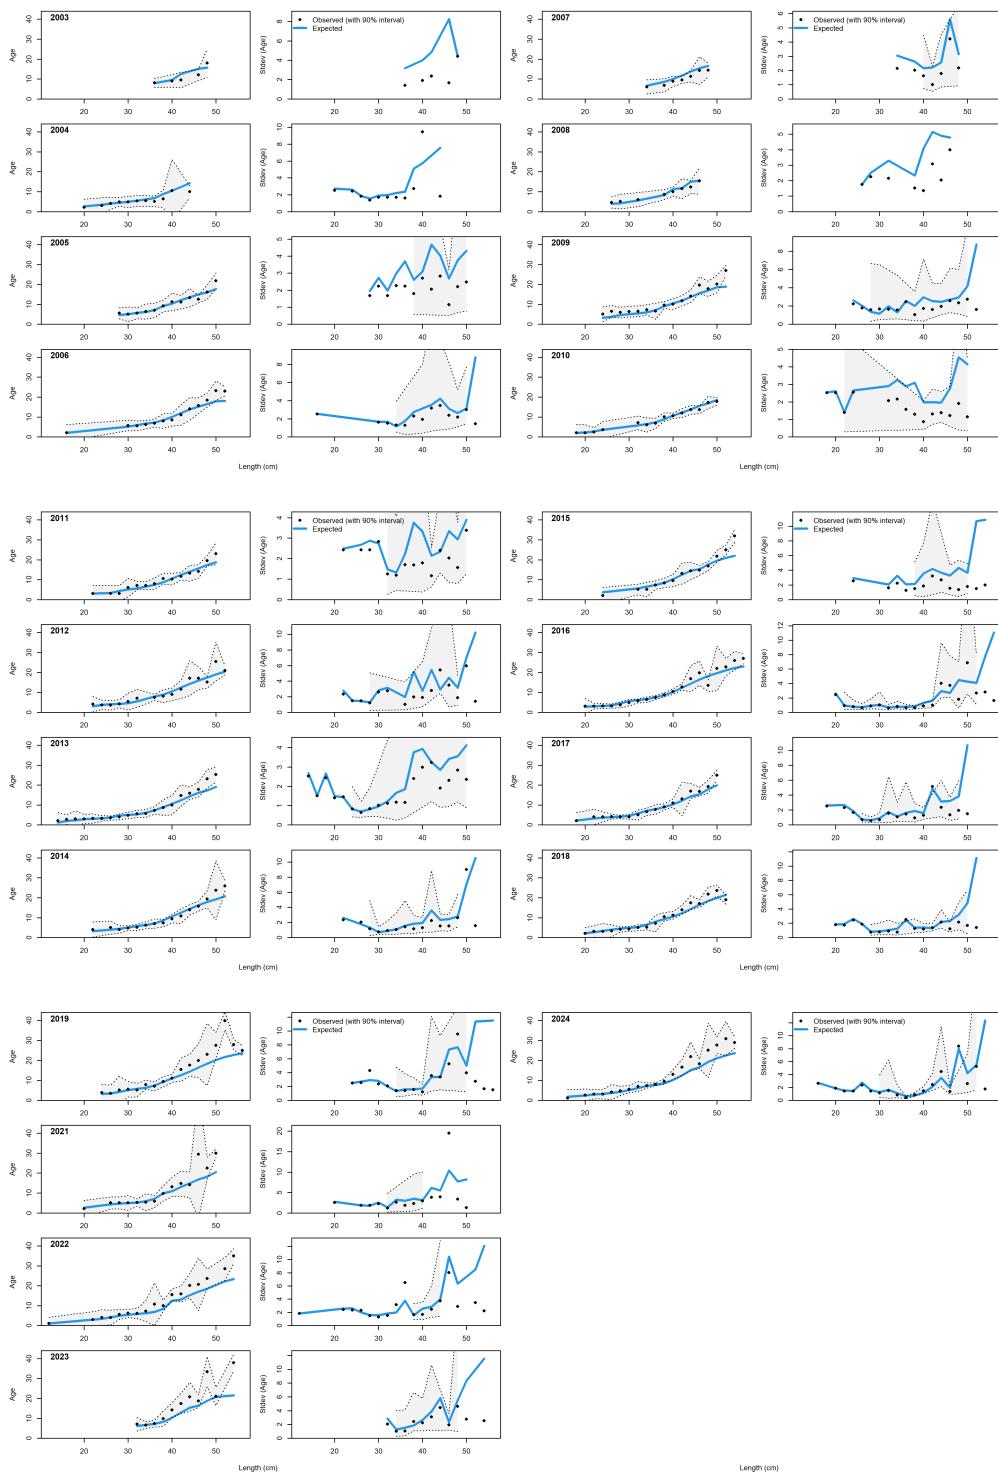

Figure 42: Observed and expected age-at-length with 95% confidence intervals (left) and observed and expected standard deviation of age-at-length with 95% confidence intervals (right) for the WCGBTS.

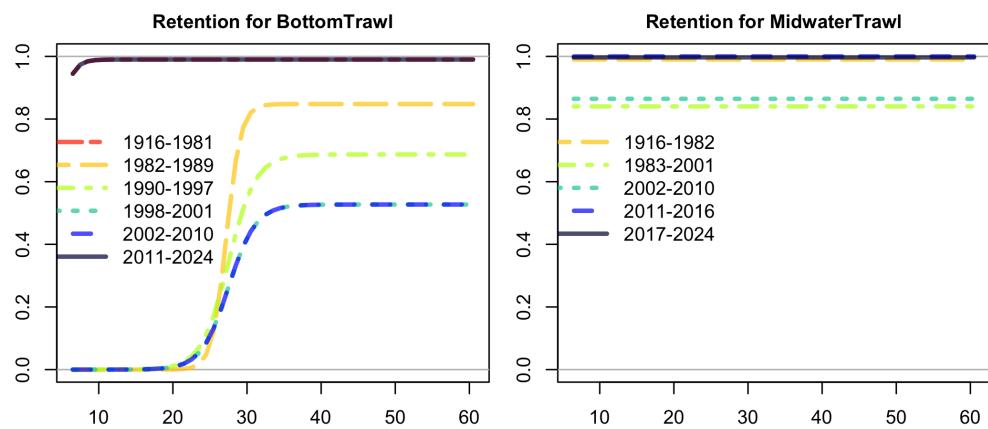

Figure 43: Estimated retention curves by time block for bottom and midwater trawl fleets.

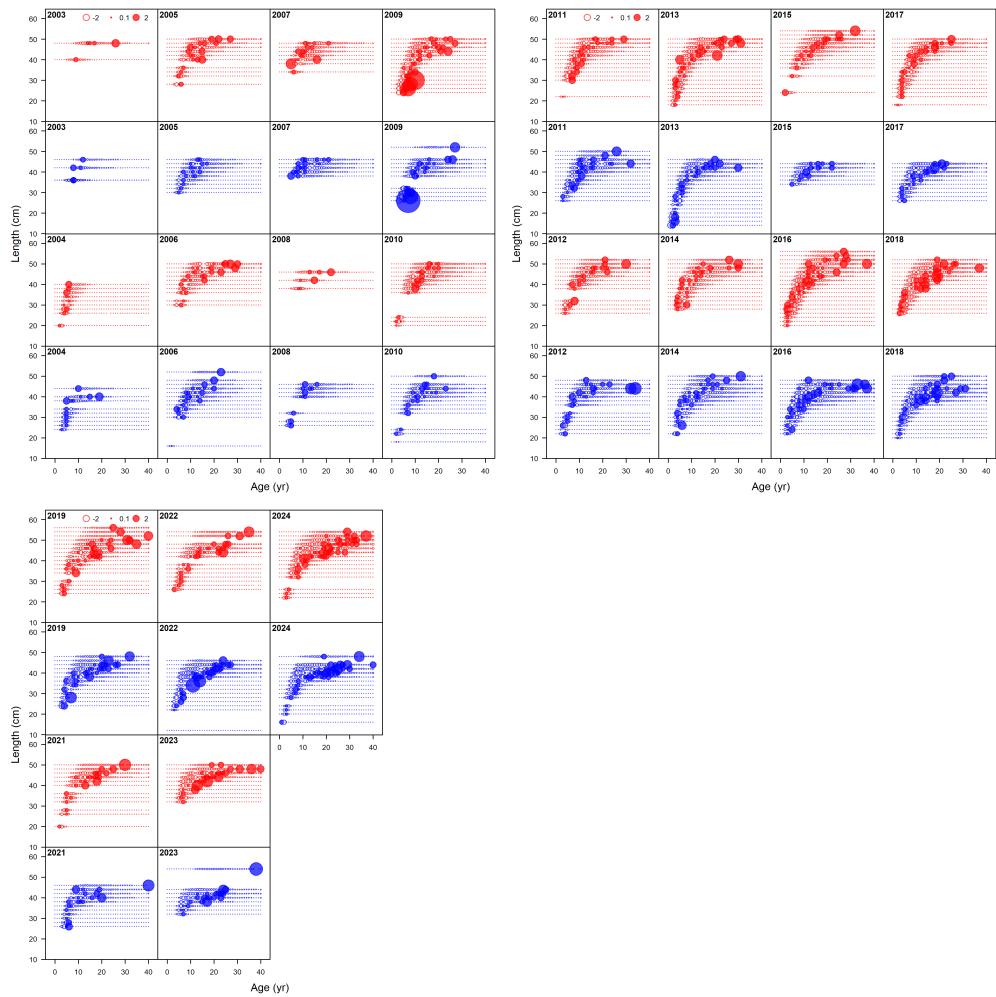

Figure 44: Combined age and length frequency data for all years from fishery (retained catch) and survey length frequency data (points) for females (red) and males (blue).

### 6.2.5 Timeseries

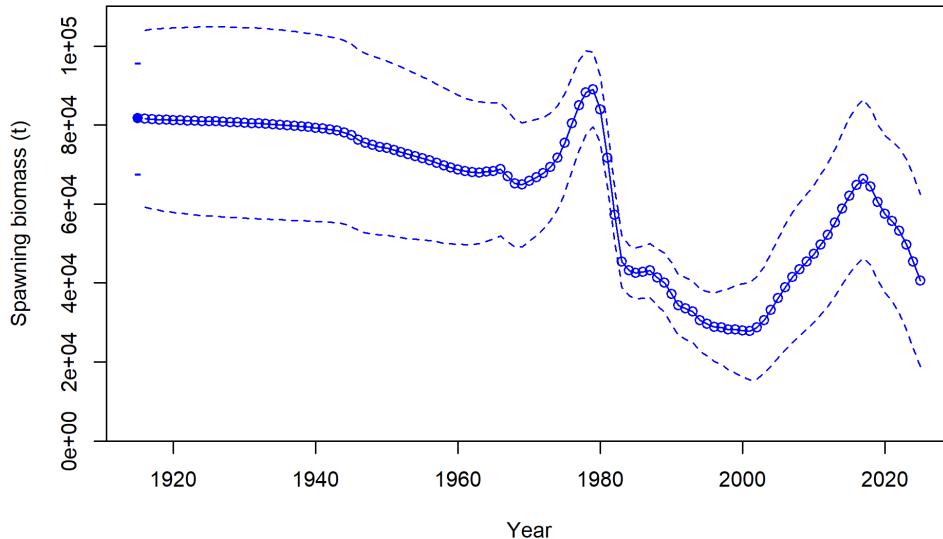

Figure 45: Predicted spawning biomass (thousand mt) for widow rockfish using the base assessment. The solid line is the MLE estimate, and the dashed lines depict the approximate asymptotic 95% confidence intervals.

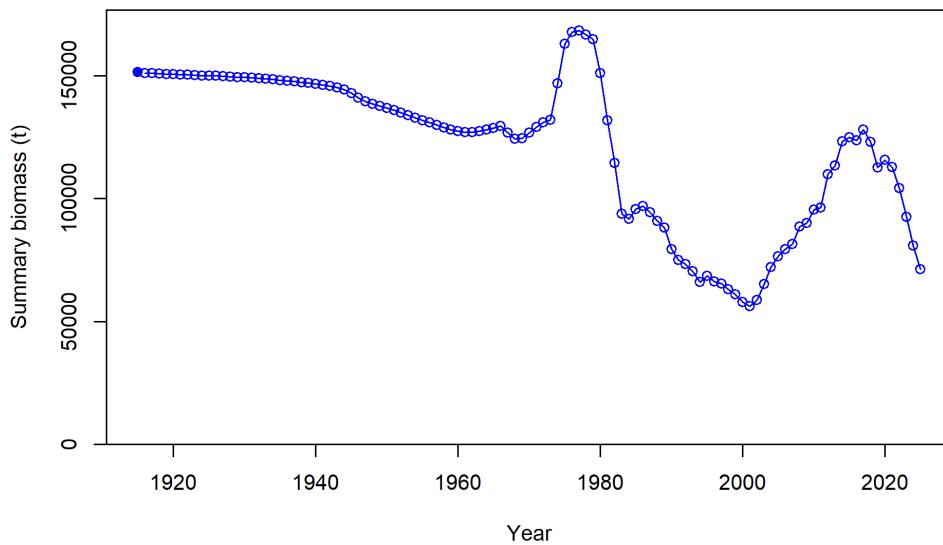

Figure 46: Predicted summary biomass (age 4+) from the base model.

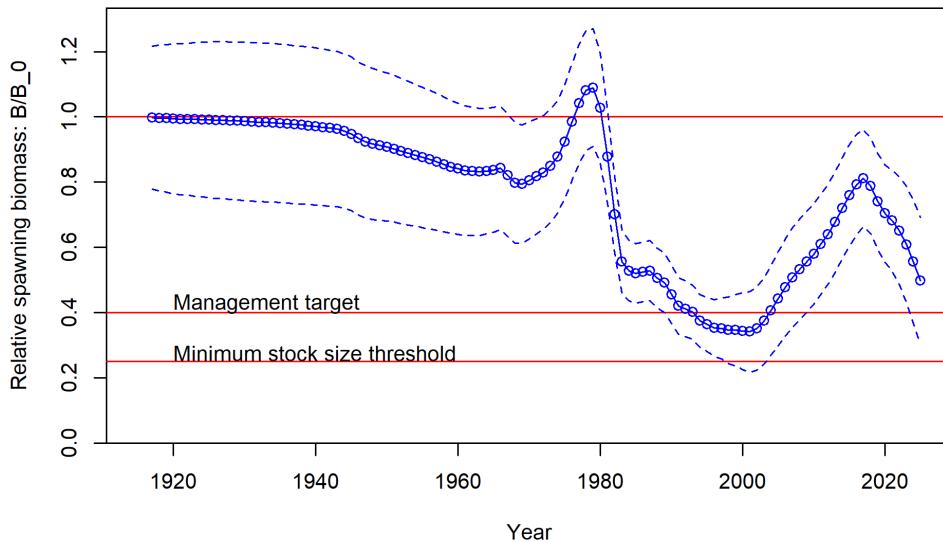

Figure 47: Predicted relative spawning biomass from the widow rockfish base case assessment. The solid blue line is the MLE estimate, and the dashed lines depict the approximate asymptotic 95% confidence intervals. The red lines show the equilibrium level (100%), the management target of 40% of unfished biomass, and the minimum stock size threshold of 25% of unfished biomass.

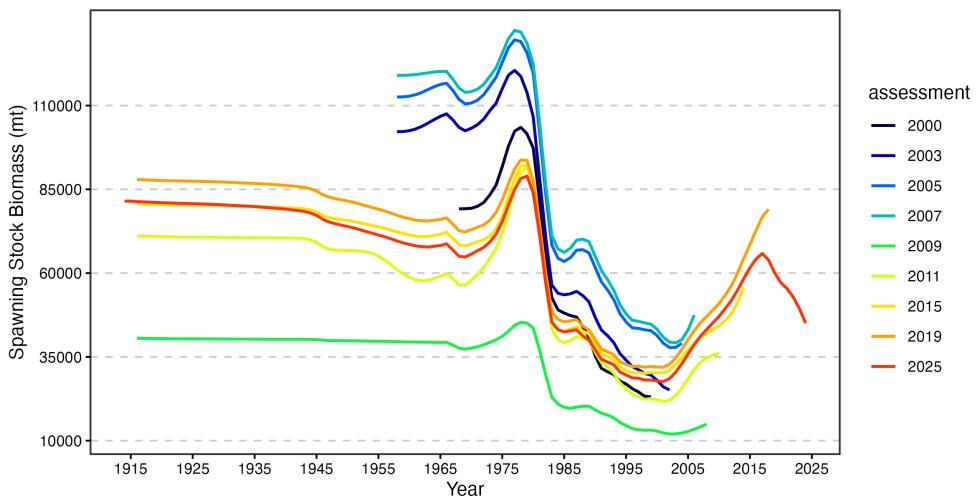

Figure 48: Predicted spawning biomass (2011 onward) or spawning output (2000-2009) from past assessments in comparison with the current assessment.

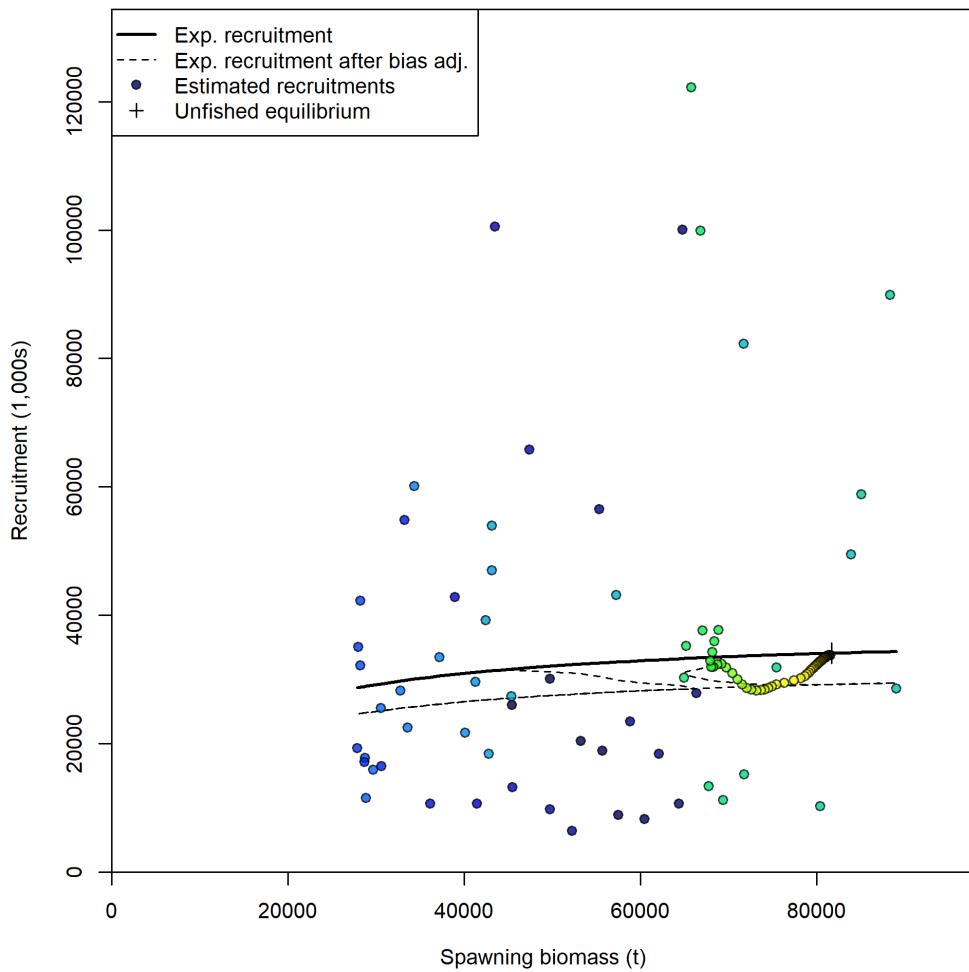

Figure 49: Estimated recruitment and the assumed stock-recruit relationship (black line).  
The dashed line shows the effect of the bias correction for the lognormal distribution.

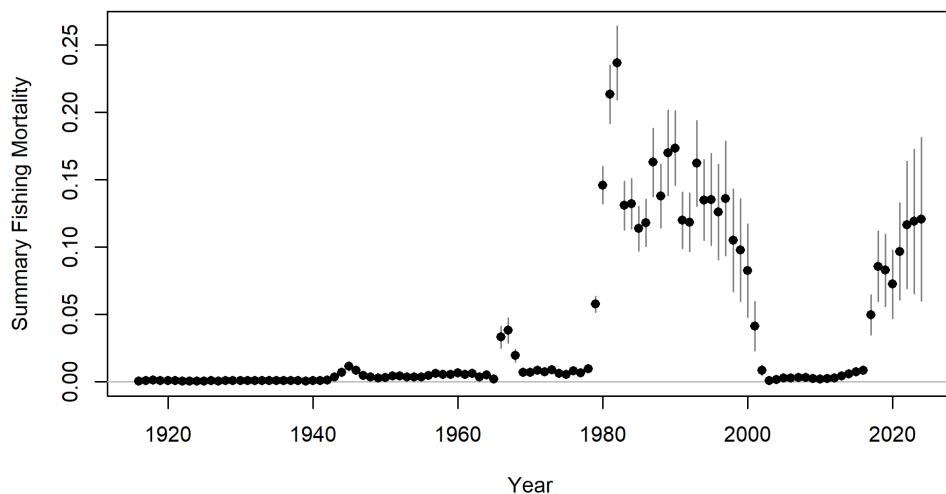

Figure 50: Plot of the summary fishing mortality for each year of the model with 95% confidence intervals.

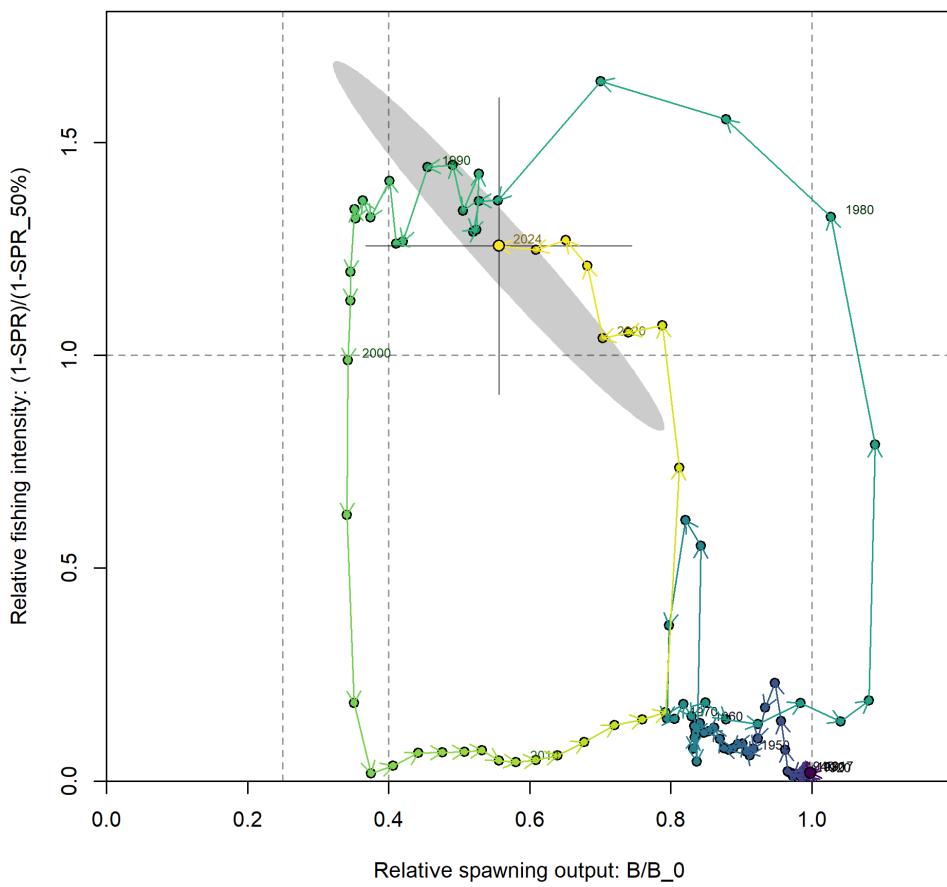

Figure 51: Phase plot of relative  $(1-SPR)/(1-SPR_{50\%})$  (y-axis) and depletion (x-axis) for widow rockfish.

### 6.3 Model Diganostics

#### 6.3.1 Sensitivity analyses

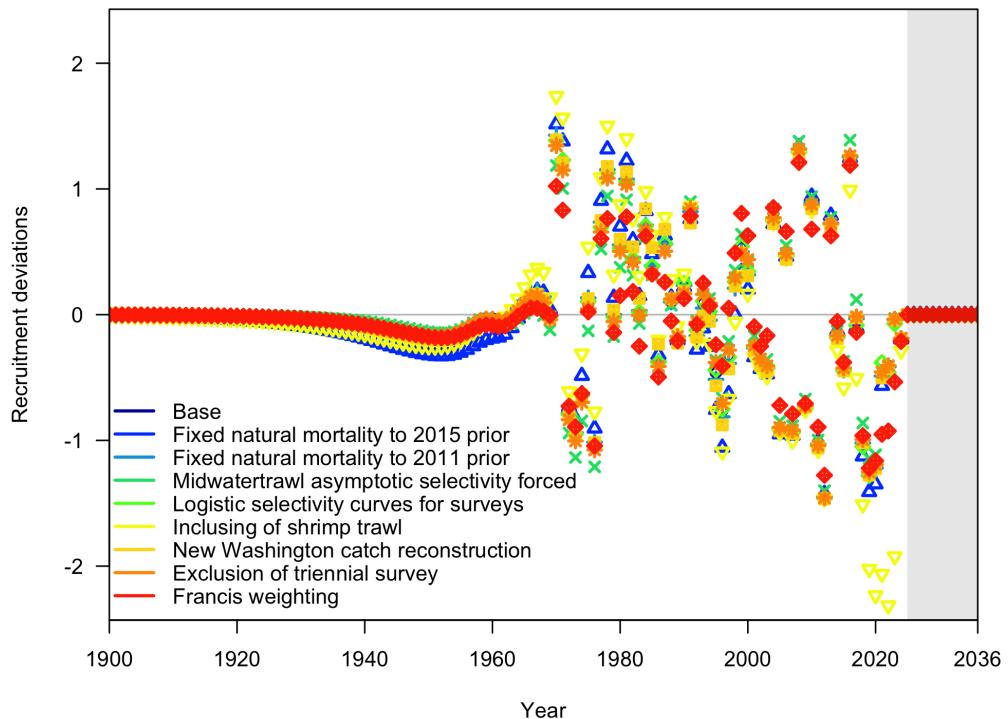

Figure 52: Estimates of recruitment deviations for sensitivity models.

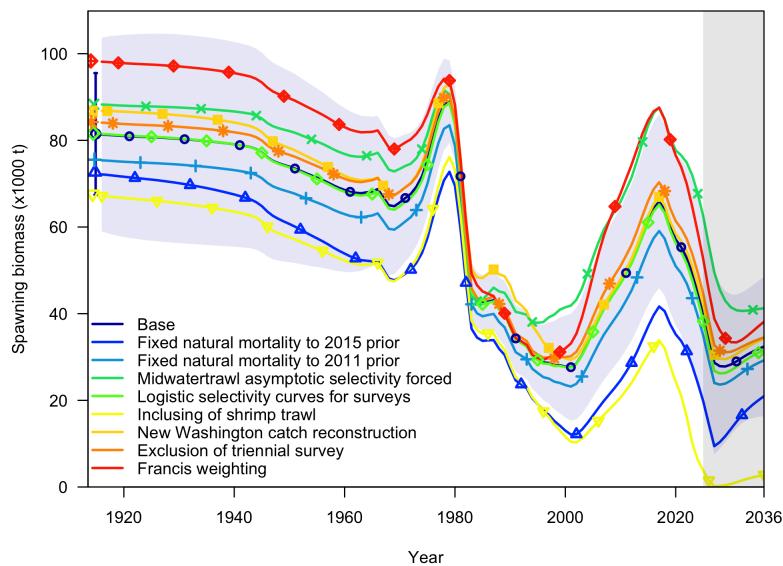

Figure 53: Spawning biomass (with 95% confidence interval around the base model) for the base model and sensitivity runs. (no rec dev)

Figure 54: Comparision of model estimated quantities for 2025, given as percent of the base model estimated value, by sensitivity run.

### 6.3.2 Retrospective analysis

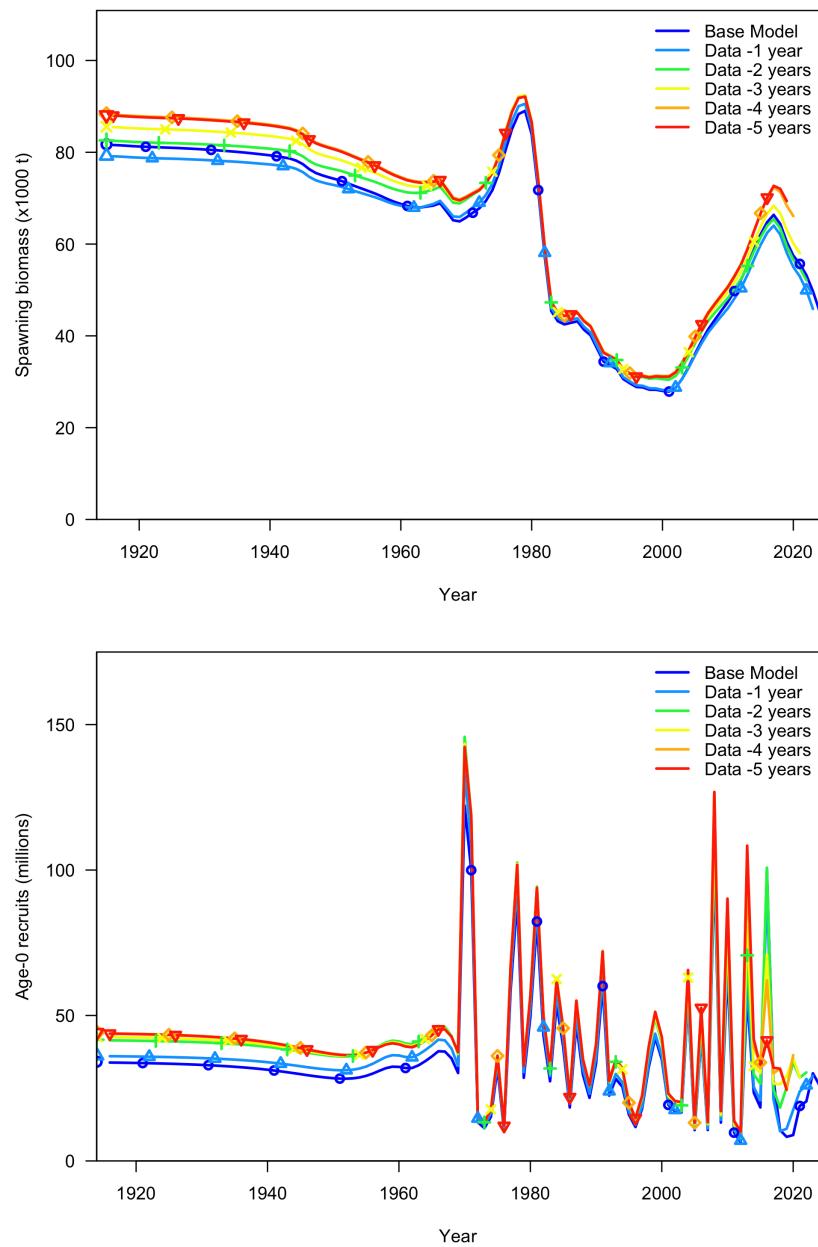

Figure 55: Five-year retrospective estimates of spawning biomass (top) and recruitment deviations (bottom).

### 6.3.3 Likelihood profiles

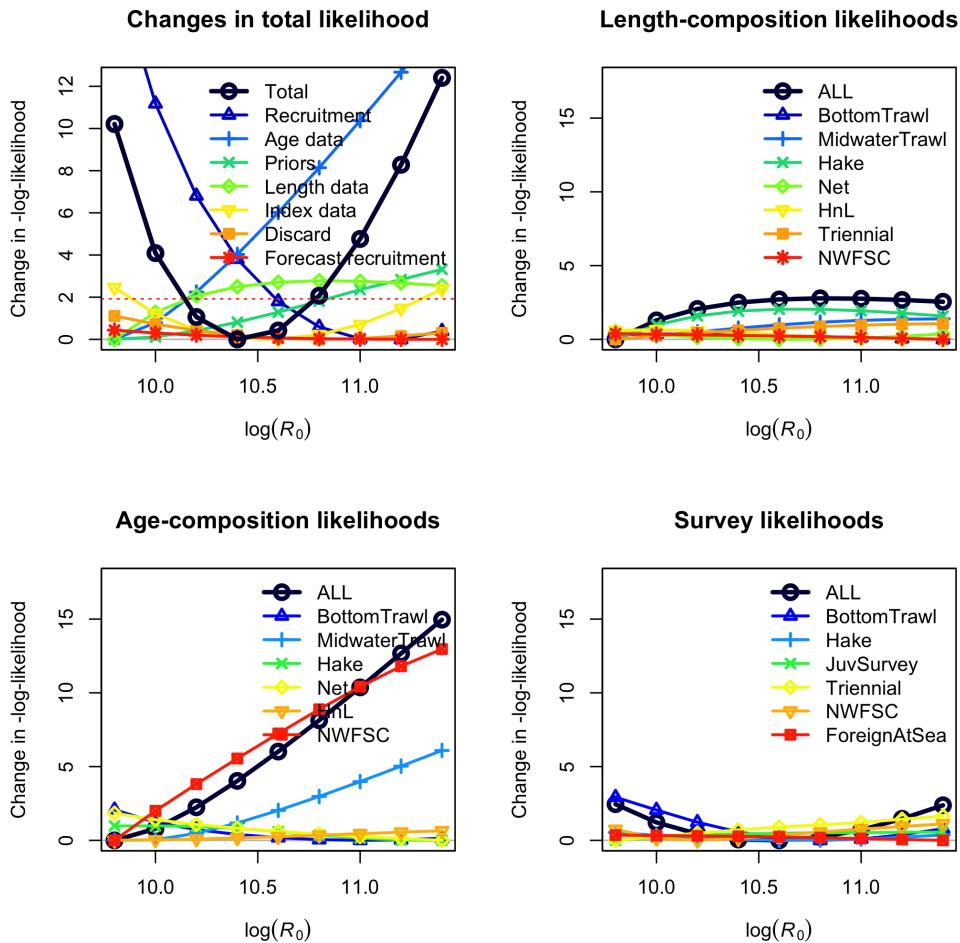

Figure 56: Likelihood components in the likelihood profile for unfished equilibrium recruitment ( $R_0$ )

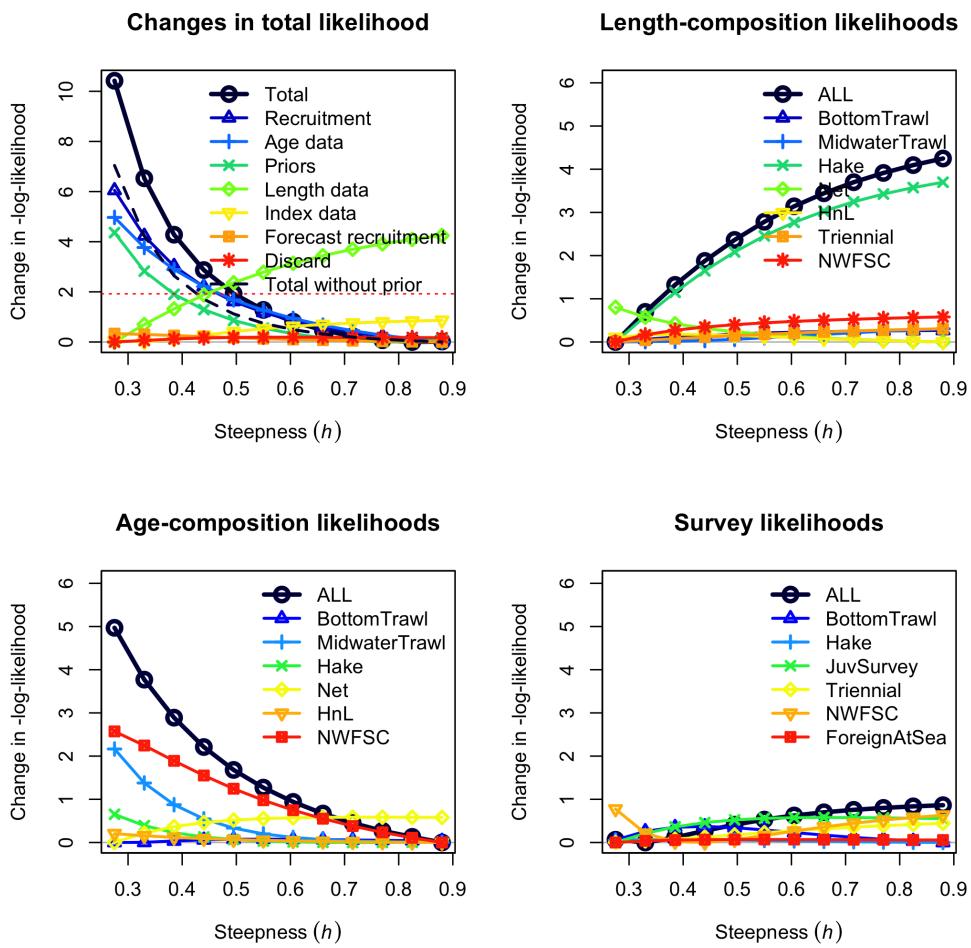

Figure 57: Likelihood components in the likelihood profile for steepness (h).

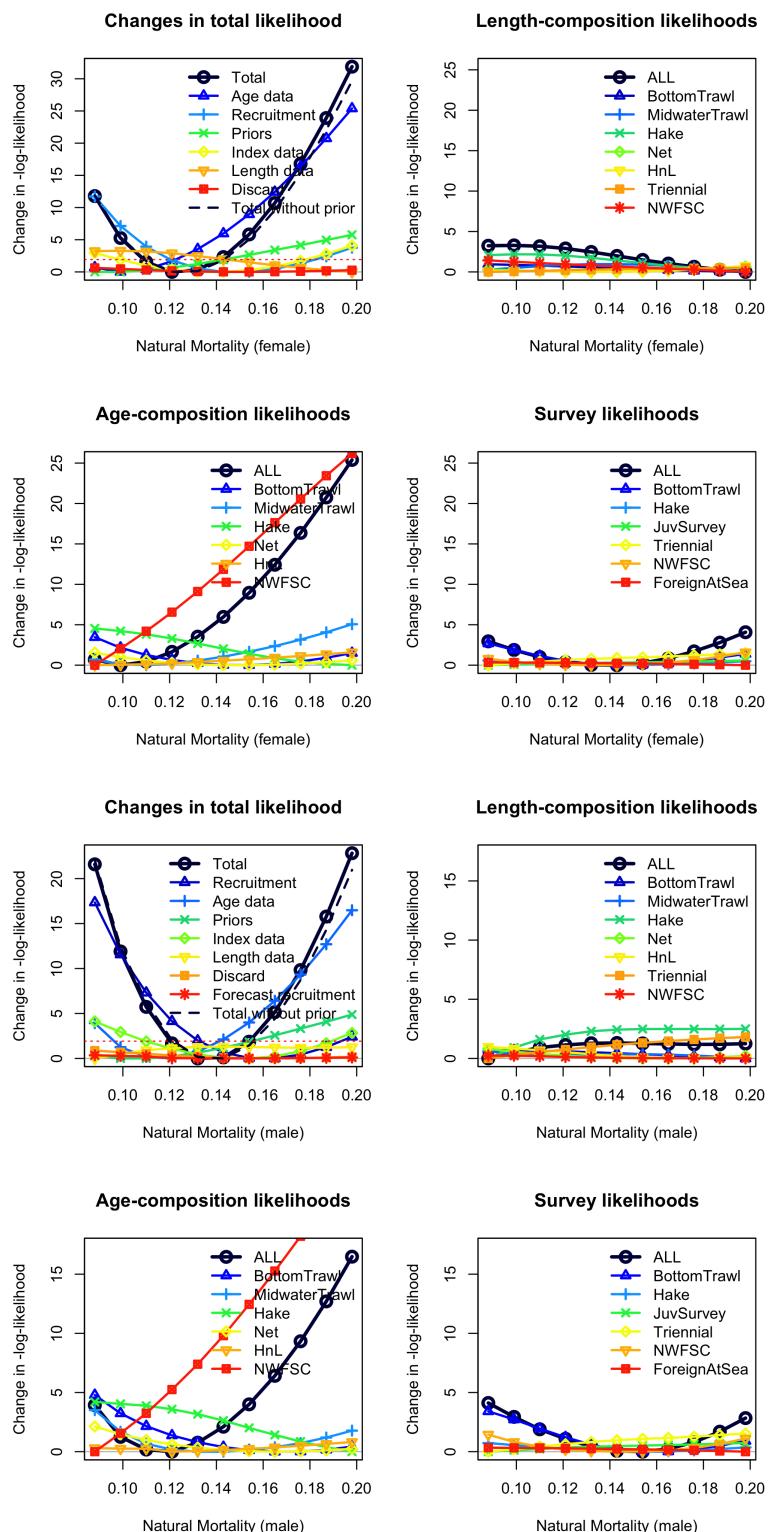

Figure 58: Likelihood components in the likelihood profile for natural mortality (M).  
Note: male and female natural mortality are set to the same value.

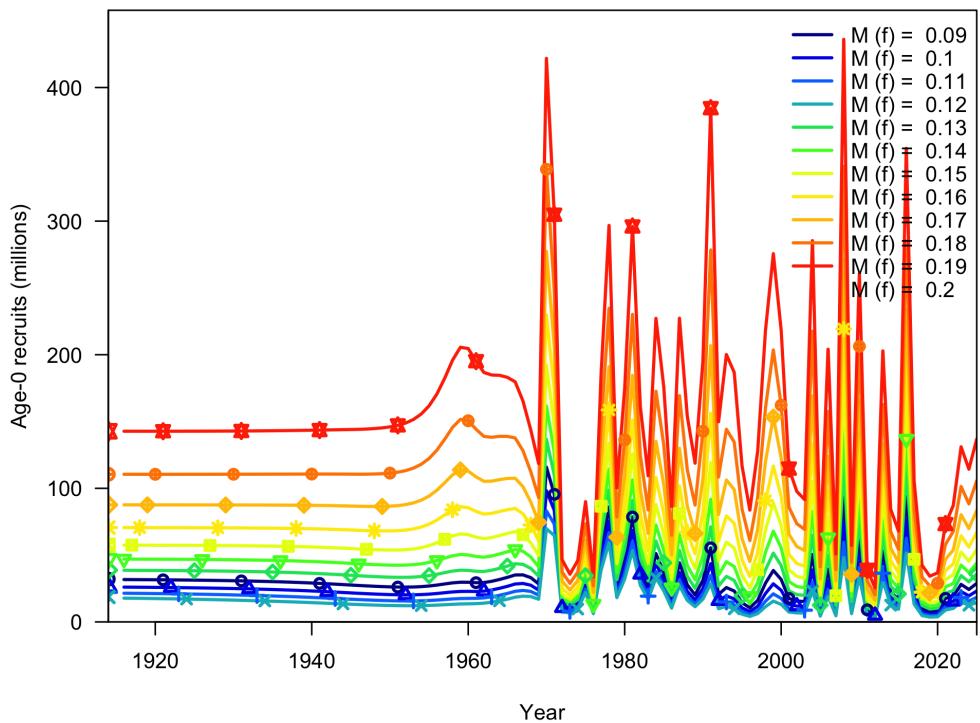

Figure 59: Time series of recruitment estimates for models with different fixed values of natural mortality (M)

#### 6.4 Management

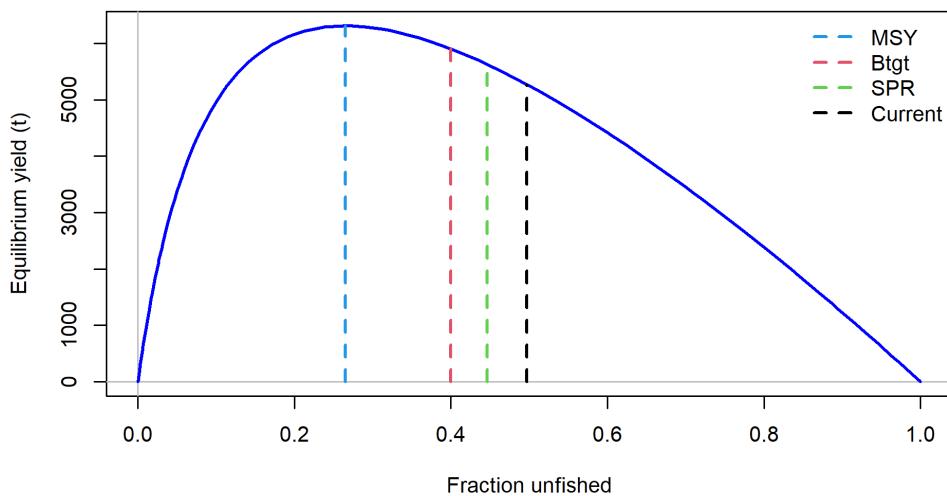

Figure 60: Estimated plot of equilibrium yield vs the fraction of unfished biomass.

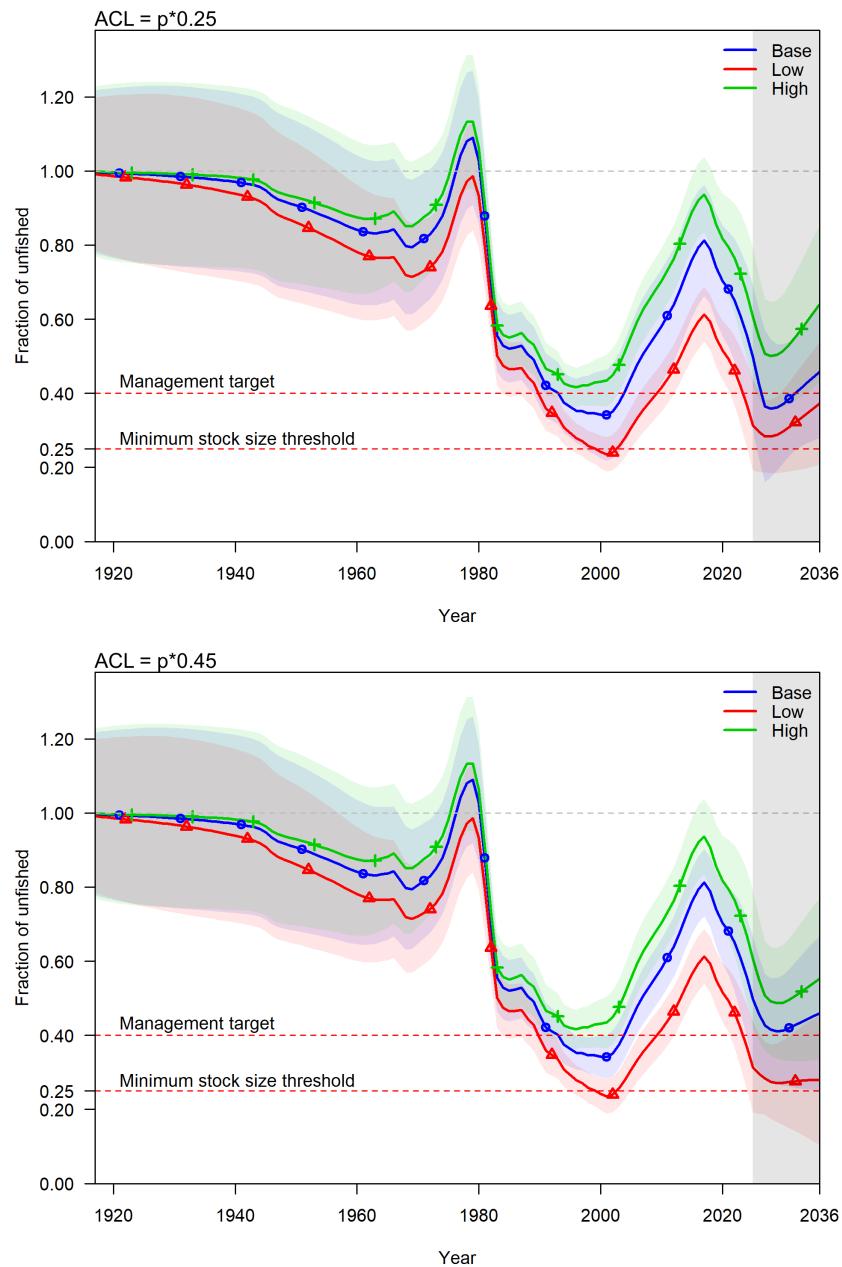

Figure 61: Base model, low state of nature, and high state of nature spawning biomass trajectories under three catch scenarios: constant catch of 9000 mt,  $ACL = p*0.25$ ,  $ACL = p*0.45$  for 2027 to 2036. The shaded areas indicate the 12.5% and 87.5% lognormal quantiles of spawning biomass.
